INDEX TO VOLUME III.

[The Names of the Authors whose writings are abstracted or reviewed in the 'London Medical Record' are given at the head of the List under each Letter.]

ABEILLE, M., 639; Albertoni, Dr., 424; Alling, Dr., 261; Andral, M., 324; Annandale, Mr. T., 89, 90, 445; Arloing, M., 453; Arlt, Dr., 505; Arnold, Dr. J., 582; Atkins, Dr. R., 409, 467, 499; Aubert, M., 635; Audé, Dr., 151; Auger, M., 26; Auzouy, Dr., 154; Aveling, Dr. J. H., 122; Azam, M., 327
Abdomen: penetrating wounds of, treated antiseptically (Mac Ewen), 343; pistol-shot wound of (O'Meagher), 534; succussion-sound in tumours (Laboulbène), 659
Abortion: metrorrhagia after (Zaunschirm), 223; in America, 508; spontaneous (Leblond), 546; case of, 556; periuterine hæmatocele after (Schrann), 637
Abscess: perityphlitic (Gourley), 276
Absinthe: 268
Absorption of medicaments by infants from mother's milk (Lewald), 546
Academy of Sciences in Paris: prizes of, 28; proceedings of, 453, 598, 639, 695; of Medicine, prize of, 75; proceedings of, 402, 506, 596, 638, 694; legacies to, 698; Royal Irish, grants of, 219
Accommodation: use of Calabar bean in impairment of (Magnus), 186
Aconite: poisoning by (Waddell), 549
Aconitin: action of on heart (Lewin), 520
Addison's disease (Pye-Smith), 483; (Greenhow) *rev.*, 645
Adenoid vegetations in pharynx (Politzer), 313
Adenopathy: bronchial (Lereboullet), 53
Ague: emetics in cold stage of (Hall), 99
Air-passages: plum-stone in (Wiesener), 86; foreign body in (Delery), 536
Albumen: pathological (Birot), 116; compounds of (Heynsius), 580; in urine of epileptics (Karrer), 671
Albuminates: nutritive value of (Panum), 221
Alcohol: effect of, on health (Palmer), 19; mania from, in France, 44; lecture on (Richardson), 62, 77, 93; epilepsy from (Drouet), 260; use of, in disease (Morris) 324; action of (Lussana and Albertoni), 424
Alcoholism: strychnia an antidote to (Morey), 391
Aldehyde: action of (Lussana and Albertoni), 424
Aleuritis triloba: oil of (Oxamendi), 373
Alimentary canal: injection of water into (Dammann), 437
Alimentation in disease (Flint), 14
Alkalies: use of (Waggoner), 25
Aloin: changed, action of (Craig), 451
Amaurosis from sudden cessation of menstruation (Samelsohn), 230
America: abortion in, 508
Ammonia: treatment of snake-bites by, 332
Amputation: statistics of (Morton), 292; of thigh, supracondyloid (Stokes), 537
Amyl: nitrite of, action on blood-corpuscles and temperature (Ladendorf), 18; chronic gastralgia cured by (Forrest), 148; remedial value of (Solger, etc.), 168; in epilepsy (Mitchell), 228; (McBride) 360; in melancholia (Schramm), 344; action of (Samelsohn), 479
Anæmia: cerebral (Fothergill), 328
Anæsthesia: by intravenous injection of chloral (Oré), 9; spontaneous (Rendu), 530
Anæsthetic: chloral as an, in labour (Chouppe), 391

Anæsthetics: influence of, on temperature (Simonin), 325
Anatomy: new school of, 603
Anconeus tertius (Galton), 196
Aneurism: popliteal, cured by compression (Pizzorno), 9; remarks on (Mauder) 90; of aorta treated by iodide of potassium (Mathews), 99; of innominate artery, distal operation for (Ensor), 137; of arch of aorta (Webb), 147; treatment of (Verneuil) 149; of external carotid artery cured by compression (Marques), 150; traumatic femoral treated by Anel's operation (Audé), 151; spontaneous, pathogeny of (Köster), 389; dissecting, of thoracic aorta (Hedenius), 482
Angina pectoris: sudden death from (Wilson), 148; new form of (Lasègue), 621
Angiaphrosia (Piory), 597
Aniline: preparation of bony tissue with (Ranvier), 211; poisoning by, 396
Animals: domestic, thermometry of (Siedamgottzky), 385
Ankle: resection in compound fracture of (Echeverria), 166
Annales des Maladies de l'Oreille et du Larynx, 395
Anthrax: and furunculus of face (Labattu), 344; antiseptic subcutaneous injections in (Davaine), 452
Antiseptic: incisions an aid to diagnosis (Annandale), 90; osteotomy (Vollmann), 216; method, Lister's (Thiersch), 317, 334; treatment of penetrating wounds of thorax and abdomen (Mac Ewen), 343
Anuria: hystero-epilepsy with (Bourneville), 486
Anus: fissure of, treated by chloral (Créquy), 635
Aorta: abdominal, aneurism of, treated by iodide of potassium (Mauder), 99; compression of, in *post partum* hæmorrhage (Schnabel), 123; thoracic, aneurism of (Webb), 147; (Hedenius), 482
Aortic regurgitation: treatment of (Balfour), 117
Aortitis: chronic (Jousset), 526
Apocynum cannabinum: in dropsical affections (Hutchins), 541
Apomorphia: physiological and therapeutic properties of (Brochin), 57; action on mammals and on the frog (Harnack), 160; subcutaneous injection of (Prévost), 183; (Duncan), 541
Apoplexy: diagnosis of, causes of (Jackson), 398; pulmonary, in an infant (Budini), 533
Appendix vermiformis: perityphlitic abscess from inflammation of (Gourley), 276
Apsithuria (Cohen), 388
Aquarium at Naples, 108
Arachnoid cysts (Braine), 679
Arctic cold, influence of, 460
Argyria: case of (Riemer), 584
Army: health of the, 140; pulmonary consumption in (Welch), 278
Arnica: tincture of (Smith), 636
Arsenate of iron, soluble (Clermont), 139
Arsenic: in nodular arthritis (Groussin), 485; eaters of in Styria (Knapp), 612; treatment of paludal fevers by (Sistach), 634
Arteritis: opacities of vitreous humour from (Poncet), 328
Artery: popliteal, aneurism of, cured by compression (Pizzorno), 9; innominate, distal

operation for aneurism of (Ensor), 137; external carotid, aneurism of, cured by compression (Marques), 150; femoral, traumatic aneurism of, treated by Anel's operation (Audé), 151; internal iliac, ligature of, for wound of gluteal (Landi), 291; facial, compression of, in epistaxis (Robinson), 373
Arthritis: deformans (Duplay), 372; nodular, treated by arsenic and arsenical baths (Groussin), 485
Artificial: arms, etc., collection of (Stump) *rev.*, 283; respiration (Mattison), 543
Ascites: remarkable case of (Jamieson), 226
Asphyxia: of new-born infants, electricity in (Zaunschirm), 312; gases of blood and lymph in (Tschiriew) 478; by bronchial foam (Piory), 597
Aspiratory puncture: in hernia (Bouisson) 343; of bladder (La Garde), 676
Association: British Medical, 508; British, for Advancement of Science, 555
Assurance offices and medical men, 453
Asthma: grindelia robusta in (Smith), 408
Ataxy: locomotor (Rey), 678
Atheroma (Fothergill), 585
Atresia: of female genital organs (Puech), 546
Atrophy: progressive muscular (Bernhardt), 221; (Pierret and Troisier), 341; methodical treatment of (Dally), 444; protopathic muscular (Charcot and Gombault), 621
Atropia: combined with chloral and morphia (Bartholow), 10; action on perspiration (Vulpian), 132, 397; action on salivary glands (Vulpian), 381; as a nervous stimulant (Smith), 390; poisoning by (Hedler), 633
Auditory meatus, closure of (Schwartz), 329
Auditory vertigo (Brown-Séquard and Labadie-Lagrave), 287
Auricle: of ear (Seely), 687
Auricles: connection between, in cases of spinal curvature (Perreymond), 668
Auscultation of children (Cuzzi), 657
Avulsion of forearm (Parona), 590

BACHER, Dr. S., 393; Baer, Dr., 50; Bailey, Dr. F. H., 618; Baizeau, Dr., 179; Balfour, Dr. G. W., 117; Bantock, Dr., 107; Baraban, Dr. L., 450; Barber, Dr., 232; Barker, Dr. F., 102; Barnouvin, M., 228; Bartlett, Mr. H. C., 599; Bartholow, Dr., 10; Bastian, Dr. H. C., 507; Becker, Dr. L., 180; Becker, Dr. O., 91; Becquerel, M., 4; Bedoin, Dr., 42; Beely, Dr., 262; Béhier, Dr. 72; Bellière, M., 393; Benedikt, Dr., 211; Beneke, Dr., 400; Bergeron, Dr., 154, 695; Bernhardt, Dr., 221, 616; Bernstein, M. J., 667; Bertrand, M., E., 505; Bertholdt, Dr., 245; Berthold, Dr., 619; Besnier, Dr., 361, 526; Bigelow, J. M., 587; Billroth, Dr., 589; Binet, Dr. M., 229, 423; Binz, Dr., 82; Birch-Hirschfeld, Dr., 7; Bird, Mr. Golding, 37, 105; Birot, M., 116; Bizzozzo, Dr., 185; Blache, M., 262; Blackwood, Dr., 154; Blake, Dr., C., 161; Blake, Dr. C. C., 647; Blanche, Dr., 155, 211; Bland, Dr., 26; Blot, M., 547; Blyth, Mr. A. W., 518; Bock, M. C., 354; Boddard, Dr. R., 618; Boeckel, Dr., 630; Boissin, M., 694; Bonnemaison, Dr., Bolling, M. G., 582; Bouchardat, M., 485; Bouchacourt, M., 595; Bouchardat, M., 165, 620; Bouchut, M., 226, 294, 633; Bouillaud, M., 695; Bouisson, Dr., 343; Bourne-

- ville, Dr., 322, 486, 593; Bowditch, Dr., 109, 437, 517; Bozeman, Dr. W., 9; Brakenridge, Dr., 593; Brandt, M., 274; Braun, Dr. H., 178; Bree, Dr. C. R., 139; Briand, Dr., 487; Brickell, Dr., 358; Brière de Boismont, Dr., 378; Brochin, M., 57; Brodowski, Dr., 522; Brown, Dr. C., 104; Browne, Dr. Crichton, 273, 679; Brown-Séquard, Dr., 287; Bruen, Dr., 540; Bruglocher, Dr., 74; Brunton, Dr. J., 248; Brunton, Dr. Lauder, 87, 98; Bryan, Dr. A., 403; Bryant, Mr. T., 90; Buckingham, Dr., 409; Bucquoy, M., 361, 619; Budge, Dr., 470; Budin, M. P., 120, 533; Bull, Dr., 134; Burchard, Dr., 73; Burrow, Dr., 101; Busenlechner, Dr., 530
- Bacteria** in perspiration (Eberth), 582
- Baldness** (Pincus), 329
- Balloon accident**, 268
- Bandage**: plaster of Paris, new method of applying (Wackerhagen), 9
- Baptism**: antenatal (Hubert), 242
- Baths**: cold and sea, influence on organ of hearing (Guye), 231; tepid, in febrile disorders of infants (Meyer), 532
- Beds**: insulation of (Wegenhals), 155
- Bedstead**: improved tubular, 647
- Bee**: inoculation with poison of (Walker), 11; co-ordinating centres in (Dönhoff), 668
- Bile**: influence of injection of (Feltz and Ritter), 37, 581; in foetus (Zweifelf), 116; formation of pigments of (Tarchanoff and Maly), 177; sugar in (Naunyn), 197; pigment of, in urine (Lewin), 354; action of, on organism, 696
- Bile-duct**: effect of ligation of (Legg), 289; (Feltz and Ritter), 339
- Birth**: quadruple, 252
- Bladder**: eversion of (Thompson), 90; prolapse of, in an infant (Frua), 323; injection of (Keyes), 446; hernia of (Sätzell), 537; aspiration of (La Garde), 676
- Blood**: coagulation of, in living animal (Plösz and Györgyal), 36; vomiting of, in hysteria (Ferran), 86; circulation of, in excised organs (Heger), 157; stains of, diagnosis by microscope (Woodward) 165; (Richardson) 306; modifications of, in passage through spleen (Malassez and Picard), 194; transfusion of, after hæmorrhage from bowel (Mosler), 340; effect of lime and magnesia on alkalinity of, 436; apparatus for counting corpuscles of, 457; gases of, in asphyxia (Tschirner), 478; spontaneous coagulation of (Hénard), 598; coagulation of (Matthieu and Urbain), 613; pulverisation of, 697
- Blood-corpuscles**: red, action of nitrate of amyl on (Ladendorf), 18; diffusion of, and serum (Nasse), 666
- Blood-corpuscles**: colourless, formation of giant-cells from (Ziegler), 34; passage of, out of vessels (Purves), 37; in spleen (Tarchanoff and Swaen), 477; migration and metamorphoses of (Rouget), 520
- Bloodless operations** (Chiene and Forster), 398
- Bloodletting**: in vomiting of pregnancy (Dax), 184; remarks on (Gross), 428
- Blood-vessels**: newly formed, in general progressive paralysis (Lubimoff), 368; changes in brains of insane (Atkins), 467; connection with lymphatics (Tarchanoff), 477; of brain, changes in, from external application of water (Schüller), 580; condition of walls of, during emigration of white blood-corpuscles (Arnold), 582; of frog's web, innervation of (Huizinger), 664; properties of walls of (Mosso), 611
- Boat-races**: Oxford and Cambridge, 172
- Bone**: formation and transformation of (Virchow), 29, 45, 61; digestibility of (Etzinger), 35; preparation of tissue of, with aniline dye (Kanvier), 211; formation of (Strelzow, etc.), 614
- Bones**: cranial, traumatic necrosis of (Hutchinson), 166; false abscesses of (Gosselin), 638
- Borax**: with ergot in labour (Brown), 104
- Botany**: practical, 380
- Bowels**: peculiar affection of (Klob), 70
- Brain**: experiments on (Hitzig), 3; cysticerci in, in progressive paralysis (Gonzales), 146; excitability of hemispheres of (Braun), 178; softening of in a dog (Duret and Carville), 179; ophthalmoscopic examination in disease of (Heinzel), 214; (Hutchinson), 487; in insane, microscopic appearances of (Kempster), 229; reflex actions of (Luys), 255; optic nerve in disease of (Manz), 296; motor centres in convulsions of (Dalton, M.), 321; circulation in (Duret), 402; of insane, changes in blood-vessels of (Atkins), 467; histology of (Major), 481; changes in in fevers and inflammation (Popoff), 579; changes in vessels from application of water (Schüller), 580; excitation of by indirect currents (Sanderson), 598
- Brazil**: medical qualifications for foreigners in, 332
- Brazilian drugs** (Holmes), 492
- Breast**: phytolacca decandra in inflammation of (Firman), 101; non-carcinomatous tumours of (Monod), 162; instrument for closing, 347; of new-born infant (De Sinéty), 480; removal of tumour of by actual cautery (Létiévant), 677
- Breast-exhauster**, 203
- Breath**: fœtid odour of (Home) *rev.*, 124
- Breech-presentations**: remarkable succession of (Nourse), 248; injuries to foetus in (Ruge), 638
- Bright's disease** (Tyson), 529. *See* Kidney
- Bromhydric acid** (Wade), 263
- Bromide**: of camphor (Raymond), 58; (Trasbot, etc.), 139; (Pathault), 451; (Bourneville), 593; antagonism to strychnia (Valenti y Vivo), 374; of iron in chorea (Du Costa), 344; of lithium (Rouband), 328; of potassium in epilepsy (Otto), 120; physiological action of (Danton), 228
- Bronchial glands**: enlargement of (Lereboullet), 53
- Bronchocele**: treatment of (Mackenzie), 40
- Bufalini**, Professor: death of, 252
- Bulimia** (Lubelski), 371
- Burial**: new system of, 412
- Bursæ mucosæ**: of trachea and larynx (Calori), 353
- CALDWELL**, Dr. J. J., 359; Calori, Dr. L., 337, 353; Campbell, Dr. H. T. F., 497; Cantieri, Dr., 13; Cantilena, Dr., 569; Carles, M., 59; Carlos, Dr. D., 634; Carpenter, Dr. A., 324; Carstens, Dr. J. H., 345; Carville, M., 179; Casanova, Dr. P., 264; Caspari, Dr., 496; Caulet, M., 436; Cavafy, Dr. J., 483; Cerasi, Dr. P., 25; Chadwick, Dr. J. R., 134; Chairon, M., 694; Chalat, M., 661; Chambers, Dr. T. K., 315; Chantreuil, Dr., 685; Chapman, Mr. M. J., 554; Charcot, Dr., 189, 621; Charteris, Dr., 266; Chauveau, M., 696; Chiene, Mr. J., 399; Chiralt, Dr. V., 393; Choate, Dr. D., 673; Chouppet, Dr., 168, 393; Ciaccio, Dr., 520; Cianciosi, Dr., 587; Clark, Dr. D., 263, 372; Clark, Dr. H. A., 447; Clarke, Dr. E. H., 630; Clemens, Dr., 357; Clermont, M., 139; Clouston, Dr. T. S., 52, 499; Cohen, Dr. J. S., 388; Colomer, M., 540; Colomiatti, Dr., 52; Colrat, Dr., 369; Combal, M., 661; Corral, Dr., 356; Cossy, M. A., 617; Coulard, Dr. C., 336; Courjon, M., 438; Courty, Dr., 182; Coyne, M., 120; Craig, M., 451; Cremonesi, Dr., 152; Créquy, M., 246, 365; Cuignet, M., 677, 688; Cutter, Dr. E., 74; Cuzzi, Dr. A., 605, 657; Czernicki, Dr., 227; Czerny, Dr. V., 653
- Cæsarean section**: case of (Martin), 264; (Pinard) 546
- Caffeine**: therapeutic action of valerianate of (Paret), 295
- Calabar bean**: in impairment of accommodation (Magnus), 186
- Calculus**: cystin, in fossa navicularis (Santesson and Envall), 89; salivary (Doutrelepoint), 407
- Calosanthus Indica** (Evers), 254
- Camphor**: bromide of (Trasbot, etc.), 139; (Pathault) 451; (Bourneville) 593; antagonism to strychnia (Valenti y Vivo), 374
- Canal**: infraorbital, anomalies of (Calori), 337
- Cancer**: of stomach, liver, and lungs (Bull and Hansen), 134; progress of knowledge concerning (Yeo), 237; of stomach and other organs (Dumontpallier), 618; primary, of gall bladder (Lamétrie), 583; of breast, removed by actual cautery (Létiévant), 677
- Cannabis Indica**: effect of (Kuykendall), 500
- Cannibalism**, 700
- Cantharides**: vesicant and rubefacient action of (Cantieri), 13
- Cantharidine**: absorption of (Galippe), 162
- Caoutchouc dressings** (Besnier), 361
- Capillaries**: contractile elements in (Tarchanoff), 666
- Carbolic acid**: malignant pustule treated by (Klingelhöffer), 8; scarlatina treated by (Bland), 26; poisoning by (Warren), 104; treatment of diabetes by (Ebstein and Müller), 135; in medicine (Rothe), *rev.*, 234; use of, as an antiseptic (Thiersch), 317, 334; suppurative pneumonia treated by (Cianciosi), 587; in whooping-cough (Carlos), 634
- Carbon**: sulphuret of, treatment of atonic wounds and chronic ulcers by (Guillaumet), 137; in chronic ulcers (Michel), 166
- Carbonic oxide**: medico-legal diagnosis of poisoning by (Fäderholm), 233
- Carcinoma of fundus uteri** (Goldschmidt), 153; after lupus (von Langenbeck), 523
- Carcinomatous ulcers**: central cicatrization in (Jacobson), 535
- Carica papaya** (Evers), 253
- Carlsbad**: statistics of visitors of, 316
- Cartilage**: digestibility of (Etzinger), 35
- Catalepsy**: remarkable case of, 333
- Cataract**: sympathetic ophthalmia after operation for (Klein), 296; extraction of (Chiralt), 393; iridectomy for extraction of (Grand), 410; (Dezanneau), 505
- Catarrh**: of intestine, in children (Monti), 114, 125, 141; chronic intestinal, chocolate in (Kamer), 183; nasal (Mann), 213
- Catheter**: Eustachian, forceps for keeping in position (Delstange), 313
- Cauterisation**: vesico-vaginal fistula cured by (Van Wetter and Deneffe), 201
- Cautery**: actual, uses of in surgery (Létiévant), 677
- Cavities**: pulmonary, local treatment of (Pepper), 39
- Celts**: trephining among the, 44
- Cephalotribe**: uses of (Boissary), 545
- Cerebellum**: disease of, in case of erotic mania (Hospital), 679
- Cerebral anæmia** (Fothergill), 328; fluid, seat of (Hitzig), 521
- Cerebroscopy**: medical (Bouchut), 226
- Cerebro-spinal meningitis**: topical treatment of (Domanski), 87
- Chancere**: soft (Hutchinson), 591
- Chest-wall**: graphical representations of movements of (Ransome), 401
- Chicory**: adulteration of, 698
- Child-bearing**: age at which capacity for ceases (Barker), 102
- Children**: catarrh of small intestine in (Monti), 114, 125, 141; newly-born, digestive apparatus of (Zweifelf), 116; ophthalmoscopic examination in cerebral disease of (Heinzel), 214; striped pneumonia in (Steffen), 215; laryngeal growths in (Klemm), 215; palsies of (Sinkler), 357; new-born, care of (Buckingham), 409; tepid baths in febrile disorders of (Meyer), 533; treatment of rheumatism in (Jacobi), 533; semeiology of diseases of (Cuzzi), 605, 657; syphilitic lesions of osseous system in (Taylor), *rev.*, 642; management of, by savage tribes, 699
- China**: population of, 172
- Chinchona**: in India, 76; orthography of, 188
- Chloral**: intravenous injection of for producing anæsthesia (Oré), 9; combined with atropia and morphia (Bartholow), 10; treatment of varix by injection of (Parona), 39; spinal meningitis treated by, 56; state of pupil in anæsthesia from (Budin and Coyne), 120; external application of (Pavesi), 228; in whooping-cough (Greslon), 245; in traumatic tetanus (Gontier), 246; an antidote to strychnia (Will and Charteris), 266; antagonism to picrotoxine (Browne), 273; disease of choroid after use of (Steinheim), 295; in carcinoma uteri (Fleischer), 312; in labour (Chouppet), 391; new body in urine after ingestion of (Musculus and De Mermé), 402; in sea sickness (Ober), 485; in puerperal convulsions (Portal), 546; treatment of fissure of anus by (Créquy), 635; action of (Mering), 667
- Chloroform**: pupil in anæsthesia from (Budin and Coyne), 120; in natural labour (Pajot), 154; subcutaneous injection of (Ward), 633
- Chocolate**: in chronic intestinal catarrh (Kamer), 183
- Cholera**: prevention of (Pettenkofer), *rev.*, 42; subcutaneous injection of morphia in (Milford), 355; treatment of (Hall), 440; discussion in Academy of Medicine, 506, 596
- Chorea**: rest in treatment of (Dexter), 10; postparalytic (Mitchell and Charcot), 189; eserinic a remedy for (Bouchut) 294; bromide of iron in (Du Costa), 344; electrical (Stefanini), 482; treatment by ether-spray and ice-water lotions (Fabry), 637
- Choroid**: disease after use of chloral-hydrate (Steinheim), 295
- Christianity**: practical, 411
- Cicatrization**: central, in carcinomatous ulcers (Jacobson), 535

Cigars de Joy, 171
Ciliary muscle: functions of (Warlomont), 615
Cinchona: orthography of, 188. *See* Cinchona
Cinesalgia and its treatment by faradisation
(Gubler), 143
Circulation in the brain (Duret), 402
Cirrhosis of kidney, latent (Pepper), 442
Clavicle: fracture of (Delens), 311; (Vacher),
446
Clay: eaters of, 203; burial in, 364
Climacteric change (O'Connor), 663
Climate and phthisis (De la Roche), 356
Climates: tropical, diseases of (Hinton), *rev.*
106
Clinical medicine (Gueneau de Mussy), *rev.*
218
Coca leaf, 699
Cochlea: necrotic expulsion of (Schwartz), 329
Coclea-plant: disease in, 267
Cold: treatment of, 102, 139
Colic: lead, treated by injections of warm
water (Reisland), 530
College: University, Professorship of Zoology
and Comparative Anatomy in, 155; Trinity,
Dublin, Professorship of Botany in, 651
Colorado beetle, 268
Colour: changes of, in animals under influence
of nerves (Pouche), 19; perception of
(Schoen), 232; faulty perception of after in-
juries to head (Favre), 689
Colouring agents in histology (Dwight), 190
Comedones, treatment of (Hebra), 690
Congress, International, 396
Conicæ: action of, on cutaneous sensibility
(Gubler), 183
Contum: poisoning by, 318
Conjunctiva: transplantation of rabbit's (Beck-
er), 91; grafting of (Masselon), 362; diphe-
theria of (Sattler), 577
Consanguinity and idioey (Binet), 229, 523
Consultations, medical, advice on, 412
Contractions of muscles (Strauss), 530
Convicts: lunatic, provision for (Baer), 50
Convulsions: unilateral, in acquired idioey
(Atkins), 409; puerperal, chloral in (Portal),
546
Co-ordinating centra in bee, 668
Copenhagen: medical instruction in, 316
Copper-workers: lung-diseases in (Proust), 453
Cornea: ulceration of, with encephalitis and
myelitis (Jacusiel), 297
Corpus callosum: defect of (Knox), 323
Corrosive sublimate: poisoning by, from amal-
gam plugs (Payne), 104
Corzya: cotton-wool in ears a prophylactic
of (Brunton), 98
Cotton-wool: in ears, a prophylactic and cura-
tive in corzya and sore-throat (Brunton), 98;
salicylised, 171; dressing (Gosselin), 597
Cough: in children (Cuzzi), 658
Cousins: marriage of, 188, 220
Cramp: idiopathic, treated with quinine (Bu-
senlechner), 530
Cranial bones: traumatic necrosis of (Hutchin-
son), 166
Craw-craw: filaria in (O'Neill), 170
Cremation: in Gotha, 91; in Paris, 140; re-
marks on (Ullersperger), 680
Crime: hereditary, 12; and automatism, 316
Croton-chloral: action of (Liebreich), 639;
(Mering), 667
Croup and diphtheria (Jenner and Johnson),
87
Croupous inflammation (Griffini), 575
Cry: in children (Cuzzi), 658
Crystalline lens: regeneration of (Gayat), 695
Cuissart: pneumatic (Hauke), 38
Curare: action of (Steiner), 437
Cutaneous medicine (Purdon), *rev.*, 347
Cyanosis: case of (Laboulbène), 56
Cylinder epithelium: pathology of (Griffini),
572
Cyst: dermoid, of broad ligament (Auger), 26;
(Bantock), 107; of spleen mistaken for
ovarian tumour (O'Malley), 121
Cystic sarcoma: of uterus (Cremonesi), 152
Cysticerci: in brain in progressive paralysis
(Gonzales), 146
Cystin calculus (Santesson and Envall), 89
Cysts: arachnoid (Browne), 679

Damania (Caldwell), 359
Daturine as a mydriatic (Fano), 689
Dax: winter thermal establishment of (Sales-
Girons), 42
Death: prevailing hour of, 188; ophthalmo-
scopic evidence of (Gayat), 297
Deformity: by excess in hands and feet
(Cherini), 71; from arrested development in
idiots (Meyer), 173; pelvic, dress a cause of,
284
Deglutition: application of graphic method
to mechanism of (Arloing), 453
Delirium tremens: treatment of, 11
Delusion; exploded, 396
Demarquay: M., death of, 410; bequests of,
458
Detition: causes influencing, in children
(Woronichin), 675
Descemet: membrane of (Ciaccio), 520
Dhatura: detection of (Palmer), 503; poison-
ing by (Sanders), 551
Diabetes: etiology of (Schmitz), 22; (Pink
and Heidenhain) 83; (Bock and Hoffmann)
354; (Cobart) 369; treatment by carbolic
acid (Ebstein and Müller), 135; fruit in
dietary of (Mayet), 138; nervous symptoms
associated with (Bouchardat), 165; analysis
of cases of (Andral), 324; symptoms and
treatment of (Meyer), 386; gum-arabic
cakes in (Lidd), 449; glycerine in, 453;
relation of, to food (Donkin), *rev.*, 599;
hygienic treatment of (Bouchardat), 620
Diet: Manual of (Chambers), *rev.*, 315
Dietetics: effect of (Dauverge), 407
Digestion: aids to (Bartlett), 599
Digestive: fluid in fœtus (Morignia), 5; ap-
paratus of newly born children (Zweifel), 116;
organs, diseases of in children (Cuzzi), 658
Digitals: in typhus fever (Jones), 454; prin-
ciples contained in (Schmiedeberg), 251
Dimock: the late Dr. Susan, 351
Dinitro-benzole: effects of salts of (Jaffe and
Donchin), 212
Dionæa muscipula: electrical phenomena in,
599
Diphtheria: treatment of (Oertel), 78, 95;
(Frangley), 87; relation to croup (Jenner and
Johnson), 87; clinical remarks on (He-
noch), 269; gangrene of lower extremity after
(Moroni), 388; conjunctival (Sattler), 577
Diphtheritic membrane of (Summers), 438
Dipsomania: in women (Fothergill), 186
Disease: alimentation in (Flint), 14; comple-
mentary parts of (McBride), 258; acute and
chronic (Sutton), 434; zymotic, origin of
(Hunt), 485; numerical rates of, 556
Dislocation: of wrist-joint (Tillmanns), 118;
of shoulder, diagnosis of (Hamilton), 244;
of a cervical vertebra (Berthold), 245; of
phalanges, apparatus for reducing, 251;
of shoulder and hip-joints (Kocher), 536; of
metacarpophalangeal-joint of index-finger
(Puky), 627; of fourth metacarpal bone
(Rinaldi), 627
Diverticulum: pharyngeal (Watson), 290
Dog: old softening of brain in (Duret and
Carville), 179; as a patient, 411
Dress: as a cause of pelvic deformity, 284
Dressings: fixed, new material for (Roberts),
293
Drink: morbid impulse for, 12
Dropsy: pathology and treatment of (Milli-
ken), 404
Drugs: physiological action of (Debove), 594
Drunkennes: prevention of, 299
Duchenne de Boulogne, Dr., death of, 603
Duodenum: perforating ulcer of (Leverin and
Key), 583
Dwarfish race, a, 459

Dysentery: cured without opium (Carstens),
344; nitrate of soda in (Caspari), 496

Eulenberg, Dr., 320; Evans, Mr. H. B.,
626; Evers, Mr. B., 253, 494, 635; Ewald,
Dr., 74, 208
Ear: internal, diseases of (Roosa), 90; influ-
ence of cold and sea baths on (Guye), 237;
reflex mental affections in diseases of
(Kœppe), 232; middle, treatment of inflam-
mation of (Gruber), 281; auricle of (Seely),
687
Eechondrosis: spheeno-occipital (Key), 134
Eclampsia: puerperal (Duncan), 247
Eczema: treatment of (Hebra), 691
Eggs: preservation of, 348
Elder-pith: imbedding in, for cutting sections
(Bird), 37
Electrical action: of cool-baths (Schelle), 175
Electricity: in asphyxia of new-born infants
(Zaunschirm), 312
Elephantiasis: of penis after urethral stricture
(Weir), 395; Arabum (Fayrer), 475
Embolism: and disintegrated thrombosis of
portal system (Bolling), 582; fatty, clinical
importance of (Czerny), 653
Emetic medication (Grasset), 495
Emetics: in cold stage of ague (Hall), 99;
mode of action of (Chouppe), 168; action of,
on striped muscular fibre (Harnack), 665
Emetin: action of (Polichronie), 59
Emotion: sudden, in women, producing neu-
roses (Lorain), 163; effect of, 235
Empyema: subperitoneal ante-uterine (Loh-
lein), 200
Empyema: pulsating (Lorenzutti), 525
Encephalitis: with ulceration of cornea (Jacu-
siel), 297
Enchondroma: of base of skull (Noel), 178;
case of (Schweninger), 489
Endarteritis: pathology of (Koster), 339
Endocarditis: ulcerative, and micrococcus-
embolism (Eisenlohr), 179
Endoscopy (Jurie), 406
Enterostenosis (Glax), 20
Epilepsy: treatment by bromide of potassium
(Otto), 120; masked (Auzouy), 154; nitrite
of amyl in (Mitchell), 228; (McBride), 360;
alcoholic (Drouet), 260; traumatic, relieved
by operation (Darby), 291; picrotoxic a
remedy for (Planat), 327; pathology of
(Jewell), 480; peripheral traumatic (Briand),
487; albumen in urine in (Karrer), 672
Epileptic mania (Jackson), 349
Epistaxis: compression of facial arteries for
arrest of (Robinson), 373
Epithelioma: of mouth and tongue, operation
for (Morris), 107
Epithelium: cement-substance of (Thoma),
116; pavement, regeneration of (Klebs),
523; cylinder, pathology of (Griffini), 572
Epitrochleo-anconeus muscle (Galton), 196
Ergot: rules for administration of (Hicks), 97;
use of (Brown), 104; in treatment of insanity
(Mann), 498
Ergotine: treatment of uterine tumours by
hypodermic injection of (Hildebrandt), 47
hypodermic injection of, in purpura hæmorrhagica
(Minich), 405; in acute mania (Van
Andel), 548
Erotic mania: with disease of cerebellum
(Hospital), 679
Erysipelas: pathology of (Hiller), 6; cutane-
ous (Renaut), 133; and child-bed fever
(Minor), 393; migrans (Frommel), 331; treat-
ment of (Hebra), 691
Erythema: connection of with rheumatism
(Couland), 336; treatment of (Hebra), 691
Eserine: in chorea (Bouchut), 294; hydro-
bromate of, 540; physiological and thera-
peutic effects of (Bouchut), 633
Ether: habitual inhalation of (Ewald), 208
Ether-inhaler: new, 648
Eucalyptus globulus: at Kew, 43
Eustachian tube: form and position of pharyn-
geal opening of (Urbantschisch), 553; open-
ing the (Gruber), 688
Evacuations: involuntary, in apparent health
(Lyons), 587
Exophthalmic goitre: *See* Goitre
Expiration: prolonged, significance of (Solger),
525
Extra-uterine foætation: treatment of (Thomas),
248; peritoneal (Depaul), 496;

 Face: anthrax and furunculus of (Labattu), 344
 Faculty of Medicine: in Paris, regulations of, 557
 Faecal matter: circulation of after ligation of intestine (Sales-Girons), 309
 False joint: treatment of (Volkman), 310; of humerus, operative treatment of (Dolbeau), 588
 Fashion: in medicine (Clarke), 263
 Fats: introduced into blood (Röhrig), 478
 Fatty embolism (Czerny), 653
 Febrile disorders: of infants, tepid baths in (Meyer), 532
 Feeding: artificial, by subcutaneous injections (Krueg), 592
 Feet: deformity of by excess (Gherini), 71
 Fehling's solution: influence of boiling distilled water on (Boissin and Loisen), 694
 Female sexual organs: diseases of (Schreder), *rev.*, 640
 Female surgeon of seventeenth century, 699
 Femur: gravity of compound fractures of (Güntner), 100; fracture of neck of (Schumacher), 117
 Fermentation: discussion on in the French Academy, 351
 Ferments: pathogeny of disease from (De Pietra Santa), 112
 Ferri, Dr. C., death of, 316
 Fever: theory of (Murri), 65; endemic, of Jerusalem (London), 326; use of water in (Winternitz and Tauszky), 543
 Fever, intermittent: emetics in cold stage of (Hall), 99; treatment by arsenic (Sistach), 634
 Fever, puerperal: (Minor), 303; (Miller) 684
 Fever, typhoid: insanity consecutive on (Brierley), 72; Klein's researches on (Brunton), 87; treatment of (Johnson), 87; etiology of (Jenner), 145; transfusion of defibrinated blood after hæmorrhage from bowels in (Mosler), 340; treatment of by quinine (Corral), 356; milk-diet in (Rogers), 405; changes in brain in (Popoff), 579; causes and prevention of (Duncan), *rev.*, 644
 Fever, typhus: digitalis in (Jones), 294; changes in brain in (Popoff), 579
 Fever, urinary: (Roux and Paulet), 151
 Fibroid tumours: of uterus, treatment by hypodermic injection of ergotine (Hildebrandt), 47; enucleation of (Martin and others), 103; treatment of (Stoltz), 153
 Finger: index, dislocation of metacarpophalangeal joint of (Puky), 627
 Fingers: Dupuytren's contraction of (Madelung), 326
 Fiction: a medical, 203
 Fistula: urinary, in women (Landau), 27; gastro-pulmonary (Juliusberger), 37; anal, treatment of by elastic ligature (Courtney), 182; vesico-vaginal cured by cauterisation (Van Wetter and Deneffe), 201; recto-vaginal (Guedes), 246
 Flour: action of on teeth (Cutter), 74
 Flowers: how to keep fresh, 252; in hospitals, 396
 Fœtus: digestive fluid in (Moriggia), 5; medicinal treatment of (Thorburn), *rev.*, 347; sugar in (Moriggia), 521; compression of head by forceps (Hoge), 548; injuries of in breech presentations (Kuge), 648
 Fœtuses: two, with one placenta and set of membranes (Robertson), 548

Fontanelle-bone: frontal (Gruber), 5, 386
 Forceps: compression of foetal head by (Hodge), 548; modification of (Laroyenne), 595
 Forearm: avulsion of (Parona), 590
 Foreign body: in larynx (Voltolini), 182; Leferts 222; in neck (Goldschmidt), 261; in air-passages (Delery), 536
 Formulæ: unofficial, 246, 374
 Fossa navicularis: cystin calculus in (Santesson and Envall), 89
 Fracture: transverse, of patella (Levis), 88; compound, of femur (Güntner), 100; of neck of femur (Schumacher), 119; of ankle, compound, resection in (Echeverria), 166; ununited, Dumreicher's method of treating (Nicoladoni), 181; treatment of, by transplantation of bone (Nussbaum), 198; of patella, treatment of (Spence and Teale), 199; of clavicle (Delens), 311; (Vacher), 446; of spine (Clark), 447; repair of (Leboucq), 588
 Fractures: treatment of, by suspension (Hewson), 420
 France: medical profession in, 44
 Fremitus, vocal: in pleurisy and pneumonia (Janeway), 670
 Frog: innervation of vessels of web of (Huizinga), 664; means of arresting heart of (Tarchanoff), 668
 Fruit: in dietary of diabetic patients (Mayet), 138
 Furunculus of face (Labattu), 344

 Hæmatocœle: periuterine, after abortion (Schrank), 637
 Hæmatoma auris: (Robertson), 482
 Hæmatometra: evacuation of through bladder (Simon), 345; unilateral (Puech), 549
 Hæmaturia: (Choate), 673
 Hæmoglobin: preparation of urinary pigment from (Hoppe-Seyler), 354
 Hæmophilia: a case of (Hakenschmied), 484
 Hæmorrhage: *post partum*, compression of abdominal aorta in (Schmidt), 123; injection of tincture of iodine in (Trask), 311; from wounds, arrest of (Vanzetti and Verneuil), 127; from polypus of uterus, transfusion in (Filliette), 497
 Hand: deformity of by excess (Gherini), 71; left, use of, 108
 Harelip: osteoplastic operation for (Duplay), 491
 Head: occipito-anterior positions of (Macdonald), 26; unilateral sweating of (Bryan), 403; faulty perception of colours after injuries of (Favre), 689
 Headache: nervous (Hervez de Chégoen), 197
 Heart: weakness of after railway accidents (Hood), 164; cause of first sound of (Leaming), 260; sounds of (Dezautière), 339; position of impulse of (Ransome), 401; action of jaborandi on (Vulpian), 419; action of acotin on (Lewin), 520; rhythm of beats of (Rossbach), 664; arrest of in frogs (Tarchanoff), 668; communication between auricles in cases of spinal curvature (Perreymond), 668; and arteries, pulsation of (Bouillaud), 698
 Hemeralopia: nystagmus as the result of (Nieden), 279
 Hemianæsthesia: with crossed paralysis (Soulier), 403
 Hemiplegia: from lightning (Eulenberg), 320; rational treatment of some forms of (Carpenter), 324; pathology of (Jastrowitz), 674
 Hepatitis: diffuse, blood in (Feltz and Ritter), 339
 Hereditary crime, 12
 Hermaphrodism: apparent (Schöneberg), 525
 Hernia: operation for, in a pregnant woman

(Wiesener), 89; tapping, an aid to reduction of (Labbe), 137; strangulated, umbilical, new method of operating for (Demarquay), 167; radical cure for (Dowell), 244; aspiratory puncture in (Bouisson), 244; strangulated, with perforations (Hakenschmied), 406; of bladder (Rützell), 537; strangulated, treatment of (Rigaud), 538; ventral (Glass), 676
Herpes: zoster (Bucquoy), 361; treatment of (Hebra), 691
Hip-joint: disease of (Sayre), *rev.*, 298; elements of diagnosis in disease of (Taylor), 537
Hirsuties gestationis (Slocum), 544
Histology: colouring agents in (Dwight), 190
Hopkins University, 504
Hordeiform cysts: of wrist, ignipuncture in (Dupluy), 539
Horse: obstruction of bowels in a, 604
Horses: artificial eyes for, 155
Hospital: St. Bartholomew's, a year's experience in, 32; Rotunda, lying-in, report of (Johnston), 191; new, in Paris, 556
Hôtel-Dieu of Paris in old time, 508
Humerus: diagnosis of dislocations of (Hamilton), 244; resection and reproduction of (Ricordi), 492; treatment of pseudarthrosis of (Dolbeau), 588
Hydatids: of tongue (Mollière), 56; of liver and omentum (Legg), 85; sudden death from puncture of (Martineau), 389; of lungs in Australia, 443; of liver, diagnosis and treatment of (Bertrand and Bucquoy), 619; of liver treated by incision (Risel), 673
Hydrobromates: of quinia and eseria (Boille and Gubler), 540
Hydrochloric acid, poisoning by (Legg), 84
Hydronephrosis: double (Combal and Chalot), 661
Hydrophobia, spurious (Nutt), 23; experiments on alleged remedies for, 364
Hyperidrosis: cured by diachylon plaster (Bigelow), 587
Hypodermic injection: of morphia (Alling), 261; of morphia in cholera (Milford), 355; of ergotin in purpura hæmorrhagica (Minich), 359; of ergotin in acute mania (Van Andel), 548; artificial feeding by (Krueg), 592; of chloroform (Wood), 633
Hyposulphites: treatment of scarlatina by (Bland), 26; treatment of diseases by (De Pietra Santa), 112
Hypotrophy: methodical treatment of (Dalby), 444
Hysteria: vomiting of blood in (Ferran), 86; in males (Cheadle), 485; (Fabre) 486
Hystero-epilepsy: with anuria (Bourneville and Regnard), 487
INGERSLEV, Dr., 595; Inglis, Dr. D., 674; Isham, Dr. A. B., 623
Ice in the house, 364
Ichthyosis: of tongue and vulva (Weir), 346
Identification: new means of, 235
Idiocy: and consanguinity (Binet), 229; acquired, with unilateral convulsions (Atkins), 409
Idiots: deformities from arrested development in (Meyer), 173
Illegitimacy: influence of, on mortality, 107
Indian medicinal plants (Evers), 253, 494, 635
Inebriate Asylum: New York, 12
Infant: prolapse of urinary bladder in an (Frua), 323
Infants: new-born, electricity in asphyxia of (Zaunschirm), 312; starchy food for (Korowin), 344; new-born, mammaræ of (De Sinéty), 480; tepid baths in febrile disorders of (Meyer), 532; treatment of acute rheumatism in (Jacobi), 533; absorption of medicines by, from milk (Lewald), 546; new-born, comparative weight of (Ingerslev), 594; mortality of, in New York, 603; new-born, development of Graafian follicles in (De Sinéty), 616
Infectious diseases: enlargement of spleen in (Birch-Hirschfeld), 7; acute (Gerhardt), 136
Inflammation: croupous (Griffini), 575; traumatic, changes in brain in (Popoff), 579
Infraorbital canal and nerve: anomalies of (Calori), 337
Inoculation of tubercle (Friedländer, etc.), 51
Inquests: number of, 204
Insane: fibrinous substance in pia mater of (Clouston), 52; general paralysis of (Thompson), 185; microscopic appearance of brain in (Kempster), 229; changes of blood-vessels in brains of (Atkins), 467; pathology of

general paralysis of (Clouston), 499; morbid appetites of, 650
Insanity: after typhoid fever (Béhier), 72; impulsive (Blanche and others), 154; in America, 172; rheumatismal (Duboux) 186; conditions of (Santluss), 249; relations of general practitioner to (Hunt), 360; ergot in treatment of (Mann), 498; intemperance a cause of (Ley), 498; morbid appearances in a case of acute (Atkins), 499; prison (Hurel), 499
Insect-eating plants, 364, 699
Insects: in pitcher-plant, 699
Intemperance: a cause of insanity (Ley), 498
Intertrigo: treatment of (Hebra), 691
Intestine: catarrh of, in children (Monti), 114, 125, 141; minute structure of (Watney), 177; chocolate in chronic catarrh of (Kärner), 183; treatment of sudden occlusion of, by opium (Tariote), 197; arrest of movements of, by irritation of splanchnics (Von Basch), 243; circulation of faecal matters after ligation of (Sales-Girons), 309; obstruction of, treated by gaseous enemata (Torres), 356; separation and voidance of part of (Rinteln), 444; capillary puncture of (Cuignet), 677
Intussusception: with separation and voidance of intestine (Rinteln), 444
Iodide of potassium; aneurism of abdominal aorta treated by (Mathews), 99
Iodine: tincture of, injection of, in hæmorrhage after delivery (Trask), 311
Iodoform: in granular lids (Barber), 232
Ipecacuanha: action of (Polichronie), 59; injections of (Gueneau de Mussy), 102
Iridectomy: for extraction of cataract (Grand), 410; (Dezanneau), 505
Iriderama: transmission of (Page), 281
Iron: reduced, purity of (Carles), 59; bromide of, in chorea (Da Costa), 344
Itch: in hospital and private practice (Fox), 105
Ivy-poisoning (White), 683

 Mydriatic: daturine as a (Fano), 688
 Myelitis: interstitial, with ulceration of corneæ (Jacusiel), 297; recovery from (Lyman), 487; pathology of (Hamilton), 669
 Myodiastasis: cinesalgia in (Gubler), 143
 Myoma: uterine, treated by hypodermic injection of ergotine (Hildebrandt), 47
 Myopia: discussion on, 597; and hypermetropia, simulation of, by recruits (Cuignet), 688
 Myosis: after gunshot wound (Reuling), 626
 Myxosarcoma: resection of sternum for (Mazzoni), 310

NASSE, Dr., 549, 666; Naunyn, Dr., 197; Neill, Dr., 636; Nepveu, Dr., 546, 628; Netter, Dr., 168, 265; Nicoladoni, Dr. C., 181; Nieden, Dr., 279; Noel, Dr. L., 178; Nordenström, Dr., 85; Nourse, Dr., 248; Nussbaum, Dr., 198; Nutt, Dr., 23
 Nasal douche (Robinson), 373
 Natural result, a, 604
 Nauehim: operation of waters of, in rheumatism (Beneke), 400

Neck: foreign body in (Goldschmidt), 261
 Negro: tubercular diseases in (Rawlings), 443
 Neuritis: optic (Norris), 277
 Neurogia: affections of (Luke), 306
 Neuroses: persistent, from emotions in women (Lorain), 163
 Neurosis: a singular (Knecht), 71
 Nerve: pneumogastric, division of, in cholera (Hand), 23; paralysis of (Riegel), 617; gustatory, terminations of (Sertoli), 35; inferior dental, resection of (Steller), 73; optic, appearance of, in acute disease of brain (Manz), 296; consequences of section of, in the frog (Krenchel), 338; distribution of fibres of, in human retina (Michel), 519; infraorbital, anomalies of (Calori), 337; sympathetic, disease of in neck (Guttman), 586; glossopharyngeal, vaso-dilator action of (Vulpian), 616
 Nerve-fibres: course of, in spinal cord (Bowditch), 517
 Nerve-force: origin of, 188; conversion of, into heat (Gray), 614
 Nerves: changes of colour under influence of (Pouchet), 19; tubercle in ganglia of (Colomiat), 52; vaso-motor, recent researches on (Bowditch), 109; cranial, multiple paralysis of (Frankel), 147; splanchnic, arrest of intestinal movements by irritation of (Von Basch), 243; vaso-motor, functions of (Bowditch), 437; laryngeal, experiments on (Keen), 477; degeneration of, after separation from trophic centres (Cossy and Déjérine), 617; unipolar electric excitation of (Chauveau), 696
 Nervous system: central, mechanism of (Meynert, Huguenin, and Luys), 205; diagnosis of sclerosis of (Molliré), 516; quantity of water in (Bernhardt), 616
 Nervous: dissolution (Jackson), 349, 379; disease, cases of (Jackson), 367; disease, rest in (Mitchell), 529
 Nicotine: action of, 187
 Nidation: in the human female (Aveling), 122
 Nile: water of, 651
 Nitro-benzin: poisoning by (Bruglocher and Ewald), 74; (Schumacher and Spangler), 233
 Nitrogen: experimental researches on protoxide of (Blanche), 211
 Nose, throat, and ear instruments (Rumbold), *rev.*, 395
 Nostrils: plugging the (Engelisch), 406
 Nucleoli: spontaneous movements of (Kidd and Brandt), 274
 Nursing: in Philadelphia, 252
 Nystagmus: the result of hemeralopia (Nieden), 279; hereditary transmission of (Page), 281

OBET, Dr. L. C., 485; O'Connor, Dr., 663; Oehme, Dr., 22; Oestel, Dr., 78, 95; Ogston, Dr., 225; O'Malley, Dr. J. P., 121; O'Meara, Dr. W., 534; O'Neill, Dr. J., 170; Onimus, Dr., 226; Ord, Dr., 212; Oré, M., 9; Orth, Dr., 307; Osler, Dr. W., 599; Otis, Dr., 121, 643; Ott, Dr., 306, 338; Otto, Dr., 121; Oxamendi, Dr. C., 373
 Edema: and erysipelas, cutaneous (Renaut), 133; acute pulmonary, sudden death from (Cantilena), 569
 Esophagus: and trachea, recovery after complete division of (Henschen), 490
 Old age: phenomena of, 508
 Ophthalmia: sympathetic, after cataract operations (Klein), 296; sympathetic (Grossmann), 312; gonorrhœal (Hirschberg), 363; purulent, origin and treatment of (Arlt), 505
 Ophthalmoscope: in cerebral diseases of children (Heinzel), 214; in evidence of death (Gayat), 297; in diagnosis of cerebral disorders (Hutchinson), 487
 Opium: treatment of sudden intestinal occlusion by (Tariote), 107; poisoning by (Smith), 501; detection of (Palmer), 503; treatment of psychoses by (Nasse), 549
 Optic: neuritis (Norris), 277; nerve, in acute disease of brain (Manz), 296; consequence of section of in frog (Krenchel), 338
 Oriental cleanliness and western civilisation, 603
 Ornithologists: meeting of, 396
 Os fonticuli frontalis (Gruber), 5, 386
 Osseous system: syphilitic lesions of in infants and young children (Taylor), *rev.*, 642
 Ostitis: neuralgiform (Gosselin), 638, 695
 Osteoclasia: and osteotomy from an orthopædic point of view (Nepveu), 628
 Osteoplastic operation for harelip (Duplay), 491

Osteotomy: antiseptic (Volkman), 216
Otitis: phthisical (Bellière), 393
Ovarian dropsy: and ascites (Epps), *rev.*, 697
Ovarian tumour: cyst of spleen mistaken for (O'Malley), 121; interstitial tumour of uterus mistaken for (Cremonesi), 152; cysts, suppurating (Keith), 217; rupture of (Nepveu), 546
Ovaries: Battey's operation for removal of (Vandell and McClellan), 684
Ovariectomy: drainage in (Pauli), 104
Oxaluria: intermittent (Oehme), 22
Ozæna: treatment of (D'Azambrya), 325

PAGE, Mr., 281; Paget, Sir J., 383; Pajot, M., 154; Palmer, Dr. A. B., 19; Palmer, Mr. W. S., 347; Purves, Mr. W. L., 37; Pye-Smith, Dr., 483
Pachymeningitis: cervical (Bourneville), 322
Pacinian corpuscles: structure of (Schäfer), 274
Pain: therapeutic means for relief of (Spender), *rev.*, 202
Pajot, M.: intended resignation of, 91, 187; proposed testimonial to, 459
Palate: unilateral paralysis of (Dumenil), 290
Pancreas: in new-born children (Zweifel), 116
Pancreatin (Bartlett), 599
Paracæsis: in sero-fibrinous pleurisy (Becker), 180; of pleura, abdomen, and pericardium (Ferrari-Bravo and Valtosta), 275
Paralysed parts: local temperature of (Schiff), 413, 461
Paralysis: general, the eye in (Möbche), 99; cysticercii in brain in (Gonzales), 146; theory and treatment of (Thompson), 185; cerebral lesions in (Mierzejewski), 397; development of newly formed vessels in (Lubimoff), 368; pathology of (Clouston), 499; multiple, of cranial nerves (Fränkel), 147; after diphtheria, strychnia in (Henoeh), 271; double-sided, of ocular muscles (Landsberg), 279; unilateral, of velum palati (Dumenil), 290; spinal, rare form of (Lincoln), 309; in children (Sinkler), 357; spinal, resembling infantile paralysis (Lincoln), 371; from brain-disease (Bastian), *rev.*, 507
Paraplegia: in Pitt's disease (Courjon), 438
Parliament: Italian, medical members of, 43
Patella: transverse feature of (Levis), 88; treatment of fracture of (Spence and Teale), 199
Peculiar people, 458
Pelvis: deformity of, from disease of vertebræ (Martin), 264
Penis: ligatured, case of (Fuchs), 100; and scrotum, gangrene of (Weigand), 216; elephantiasis of after stricture (Weir), 395
Pepo vulgaris: as a ténicide (Heckel), 639
Pepsin: method of estimating quantity of by colour (Grützner), 6; of commerce (Symes), 49; (Bartlett), 599
Percussion: of the skull (Hagen), 282; respiratory (Da Costa), 586; in children (Cuzzi), 658
Pericardium: puncture of (Ferrari-Bravo and Valtosta), 275; (Villeneuve), 532; (Chairon), 694
Perinæum: ruptured (Brickell), 358
Peritoneal pregnancy: (Depaul), 496
Peritonitis: acute, treated by injection of tepid water (Netter), 168; purulent, spontaneous rupture of umbilicus from (Baizeau), 197; puerperal, application of the practice of ovariotomists to (Netter), 265
Perityphilitic abscess: from perforation of vermiform appendix (Gourley), 276

Perivaginitis: dissecting fibrinous (Bizzozero), 185
Perspiration: bacteria in (Eberth), 582; anomalies of (Inglish), 674
Pessaries: use of in early months of pregnancy (Smith), 497
Pessary: ring, 601
Phagedenic sores (Simmons), 590
Phalanges: Farabeuf's forceps for reducing dislocation of, 251
Pharyngeal space: adenoid vegetations in (Politzer), 313
Pharynx: diverticulum of (Watson), 290
Phonograph: use of membrana tympani as a (Blake), 161
Phosphates: in therapeutics (Dujardin-Beaumont and Blache), 262
Phosphorescence: of dead organisms (Pflüger), 666
Phosphorus: disease from, 124; action of (Labbé), 201; in medicine (Thompson), *rev.*, 282; red or amorphous, action of (Thompson), 540; necrosis from (Magitot), 695
Phthisis: in the army (Welch), 278; and climate (De la Roche), 356; inflammatory origin of (Hutchinson), *rev.*, 646
Physical education of the young, 604
Physico-chemical forces: intervention in phenomena of life (Bequerel), 4
Physiological: action of toxic and medicinal substances (Vulpian), 271, 285, 301, 365, 381, 397, 419; diagrams (Marshall), *rev.*, 507
Phytolacca decandra: in mammary inflammation (Firman), 101
Pia mater: of insane, fibrinous substance in (Clouston), 52
Picrotoxine: antagonism to chloral hydrate (Browne), 273; a remedy for epilepsy (Planat), 327
Pigmentation: black, of tongue, 490
Pistol-shot wound of abdomen (O'Meagher), 534
Pitcher-plant: insects in, 699
Plague: bubonic, in Persia and in Mesopotamia (Tholozan), *rev.*, 105
Plants: Indian medicinal (Evers), 253, 494, 635; insect-eating, 364, 699
Pleurisy: sero-fibrinous, paracæsis in (Becker), 180; rheumatic (Lasèque), 621; vocal fremitus in (Janeway), 670
Pleuritic effusion: jaborandi in (Créquy), 246
Plum-stone in air-passages (Wiesener), 86
Pneumatic cuirass (Hauke), 38
Pneumo-hydro-pericarditis (Meigs), 164
Pneumonia: striped (Steffen), 215; acute (Jürgensen), 295; contagious (Blyth), 518; suppurative, treated by carbolic acid and oil of turpentine (Cianciosi), 587; vocal fremitus in (Janeway), 670
Poisoning: by nitro-benzin (Bruglocher and Ewald), 74; (Schumacher and Spangler), 233; lead, chronic, 80; (Renaut), 503; by hydrochloric acid (Legg), 84; by corrosive sublimate from amalgam plugs (Payne), 104; by carbolic acid (Warren), 104; by carbonic oxide, medico-legal diagnosis of (Jäderholm), 233; by strychnia, treated by chloral hydrate (Will and Charteris), 266; by conium, 318; by aniline dye, 396; by opium (Smith), 501; by aconite (Waddell), 550; by dhatura (Sanders), 551; by atropine, morphia treatment in (Hedler), 633; by rhus (White), 683
Polycystic tumour: congenital, at symphysis of lower jaw (Verneuil), 452
Portal system: embolism and disintegrated thrombosis of (Bolling), 582
Posthumous overcrowding, 332
Potentilla reptans (Maisch), 495
Pott's disease: paraplegia in (Courjon), 438
Pregnancy: herniotomy during (Wiesener), 89; blood-letting in vomiting of (Dax), 184; tubal, treatment of, by operations (Thomas), 451; mental affections during (Fürstner and Savage), 474; extra-uterine, peritoneal (Depaul), 496; use of pessaries in early months of (Smith), 497; in double uterus and vagina (Pippingsköld), 595; conditions of umbilical cord interfering with (Chantreuil), 685
Prickle-cells: in stomach of various animals (Schultze), 616
Prizes: of French Academy of Sciences, 28; of Academy of Medicine, on hygiene of infants, 75; in psychological medicine, 91; of Ateneo Propagador de las Ciencias Naturales, 187; Godard, of Academy of Sciences, 299; Boylston medical, 556
Professors and testimonials, 459
Propylamine: therapeutic uses of (Cerasi), 25

Prostate: operations for relief of advanced disease of (Thompson), 90
Prurigo (Longworth), 682
Prussia: statistics of suicide in, 76
Pseudarthrosis. *See* False Joint
Psoiasis: treatment of (Guibout), 346
Psychoses: treatment of by opium (Nasse), 549
Public Health: Manual of for Ireland (Grimshaw and others), *rev.*, 266
Publications of the month, 647
Puerperal: peritonitis, application of practice of ovariotomists to (Netter), 265; fever (Minor), 303; (Miller), 684; mania (Peter), 637
Pulmonary: apoplexy in an infant (Budin), 533; oedema, acute, sudden death from (Cantilena), 569
Punishment: capital (Von Holtzendorf), 682
Pupil: state of in anaesthesia from chloroform and chloral (Budin and Coyne), 120; variations in size of at different temperatures (Gruenhagen), 289
Purpura hæmorrhagica: hypodermic injection of ergotin in (Minich), 359
Pustule: malignant, treatment of with carbolic acid (Klingelhöffer), 8; cases of (Pollatschek), 395; treatment of (Hebra), 691
Putrid fluids: injection of (Cavafy), 483
Pyrenean waters: (Garrigou), 360

QUINTARD, Dr., 593
Quinnetum, 648
Quinine: action of (Binz) 82; as an oxytocic (Blackwood), 154; (Casanova), 264; (Smith), 496; treatment of typhoid fever by (Corral), 356; treatment of idiopathic cramp of muscles of upper limbs by (Busenlechner), 530; phosphate and salicylate of (Maury), 539; hydrobromate of (Boille and Gübler), 540; in pertussis (Bruen), 540; as a gargle in sore throat (Brakenridge), 593
RABL, Dr., 454; Rabuteau, Dr. A., 161; Ransome, Dr. A., 401; Ranvier, M., 211; Rätzell, Dr., 537; Rawlins, Dr. J. T., 443; Raynaud, Dr., 552; Reeves, Dr., 449; Regnard, M., 486; Reissland, Dr., 530; Renaut, Dr., 133, 503; Rendu, M., 530; Reuling, Dr. G., 626; Rey, M., 678; Reyher, Dr. C., 599; Richardson, Dr. B. W., 62, 77, 93; Richardson, Dr. J. B., 306; Richet, M., 598; Ricordi, Dr., 492; Riegel, Dr., 139, 617; Riemer, Dr. H., 584; Rigaud, M., 538; Rinaldi, Dr., 627; Ringer, Dr. S., 66; Rinsell, Dr., 444; Risel, Dr., 673; Roberts, Dr. J. B., 293; Robertson, Dr. A., 482, 680; Robertson, Dr. J. C., 548; Robinson, Dr. B., 373; Rochard, Mr., 1; Rogers, Dr. L. K., 405; Röhrig, Dr., 478; Roosa, Dr., 90; Rothe, Dr. C., 234; Roubaud, M., 664; Rouget, M., 520; Routh, Dr., 87; Roux, Dr., 151; Ruge, Dr. C., 638; Rumbold, Dr. T. N., 395
Rachitic deformities: treatment of (Billroth), 589
Railway accidents: cardiac weakness after injuries by (Hood), 164
Rats as food, 604
Recruits: simulation of myopia and hypermetropia, by (Cuignet), 688
Rectum: passage of hand into (Bozeman), 9; manual exploration of (Weir), 358; diseases of, in women (Jenks), 409; examination of (Jurie), 454; disease of (Evans), 626
Reflex action of the brain (Luys), 255
Resection: of inferior dental nerve (Stetter), 73; of sternum and ribs (Mazzoni), 310; of knee after gunshot wound (Meusel), 372; of humerus, reproduction after (Ricordi), 492; of the scapula (Beckel), 630
Respiration: of muscle (Danilewsky), 36; movements of (Mayer), 224; (Ransome) 401; examination of muscles of, in an executed criminal (Keen), 477; artificial, easily effectual method of (Mattison), 543; chamber, 699
Respiratory percussion (Da Costa), 586; organs in children, disorders of (Cuzzi), 657
Rest: in the treatment of chorea (Dexter), 10; in nervous disease (Mitchell), 529
Retina: concussion of (Hirschberg), 322; examination of (Berthold), 504; distribution of fibres of optic nerve in (Michel), 519
Rhamnus frangula: a substitute for castor-oil (Will), 120
Rheumatic: risks, mortality among, 219; pleurisy (Lasèque), 621
Rheumatism: atrophic scapular (Sabourin), 86; acute, treatment of (Dowse), 102; cere-

- bral (Da Costa), 164; trimethylamine in (Spencer), 200; connection of, with erythema (Couland), 336; effect of waters of Nauheim in (Bencke), 400; acute articular, expectant treatment of (Dujardin-Beaumez), 531; acute, in infants and children, treatment of (Jacobi), 533
- Rheumatism: muscular atrophy (Sabourin), 86; insanity (Dubouché), 186
- Rhinitis: chronic, treatment of (Tillaux), 625
- Ribs and sternum: resection of (Mazzoni), 310
- Ring-pessary, 601
- Ringworm: Goa powder as a cure for (Fayrer and da Silva Lima), 169
- Runmeyer, Dr. H. W.: letter concerning, 203
- Russia: midwives in, 348
- SABOURIN, Dr.**, 86; Sales-Girons, Dr., 42, 399; Samelsson, Dr., 230, 497; Sanders, Dr. R. C., 551; Sanderson, Dr. J. B., 599; Santesson, Dr., 89; Santlus, Dr., 240; Sattler, Dr. R., 577; Savage, Dr., 474; Savory, Mr., 179; Sayre, Dr. L., 298, 610; Schäfer, Mr., 274, 599; Schatz, Dr., 277; Scheele, Dr., 511; Schelle, Dr., 175; Schiff, Dr. M., 413, 461; Schmidt, Dr. W., 123; Schmiedeberg, M., 451; Schmitz, Dr. R., 22; Schnabel, Dr., 123; Schoen, Dr., 232; Scheneberg, Dr., 525; Schramm, Dr., 344; Schrank, Dr., 637; Schroeder, Dr., 640; Schüller, M., 580; Schultze, M., 616; Schumacher, Dr., 190, 233; Schwartz, Dr., 329; Schweininger, Dr., 489; Seegar, M. - Sacrifice: least, of parts in surgery (Bryant), 90
- Salicylate: of quinia (Maury), 539
- Salicylic acid: wound-dressing cotton-wool, 171; substitution of for carbolic acid (Thiersch), 317, 334
- Salivary calculus: case of (Doutrelepoint), 407
- Salivary glands: in newly born children (Zweifel), 116; action of chorda tympani on (Heidenhain), 161; (Vulpian), 381; action of laborandi on, *see* Laborandi
- Salt-baths: artificial (Siegmund), 109
- Sarcoma: round-celled, of stomach and other organs (Legg), 85; in vertebral canal (Nordenström and Key), 85; interstitial cystic of uterus (Cremonesi), 152
- Scapula: resection of (Böckel), 630
- Scarlatina: treated by hyposulphites and carbolic acid (Bland), 26; treatment of (Little), 293; convalescence from (Mahomed), 438; epidemic of (Hayden), 484; case of, in a child (Kirsch), 675
- Sciatica: and consequent muscular atrophy (Landouzy), 308
- Scientific investigations: payments for, 459
- Scleroderma (Lagrange), 105
- Sclerosis: insular (Moxon), 427; of nervous system, diagnosis of (Mollière), 516
- Scrofula (Rabl), 454
- Scurvy: with hæmorrhage in spinal cord and membranes (Nordenström and Key), 85; discussion on, 452
- Sea-sickness: treatment of by chloral (Obet), 485
- Sea-water: internal administration of (Lisle), 138
- Seborrhœa: treatment of (Hebra), 690
- Sensibility: cutaneous, action of conicine on (Gubler), 183
- Shark: capture of a, with young, 11, 299
- Sheep-pox: pathology of (Klein), 524
- Shell-implants, 284
- Shock (Falk and von Langenbeck), 214
- Short-sight: from overwork of eyes (Schnabel), 123
- Shoulder-presentations: indications against version in (Pinard), 686
- Sick-rooms, how to keep cool, 363
- Skin: transplantation of (Clemens), 357
- Skin-diseases: key to (Fox), 283; treatment of (Hebra), 690
- Skull: injuries of (Gay), 23; enchondroma of base of (Noel), 178; percussion of (Hagen), 281
- Sleep: physiology of (Pflüger), 478; produced by fatiguing stuifs (Pfeyer), 668
- Sleeping sickness of Western Africa (Gore), 87
- Small-pox: cases of (Kramer), 278
- Smell: in diagnosis of disease (Isham), 623
- Snake-bites: treatment of, by injection of ammonia, 332
- Society: Royal, grants of, 28; candidates for fellowship, 267; foreign members, 267; North London Medical, 251; scientific, at Caius College, 396; Royal Medical of Edinburgh, office-bearers, 698; West London Entomological, 700
- Soda: bicarbonate of, relief of toothache by, (Duckworth), 223
- Sool-baths: electrical action of (Schelle), 175
- Sore-throat: contagious, epidemic of (Routh), 87; quinine gargles in (Brakenridge), 593
- Spain: medical profession in, 348
- Spasm-centre: of frog (Heubel), 83
- Spectrum-apparatus: microscope (Sorby), 306
- Spheno-occipital enchondrosis (Key), 134
- Spider-bites (Modestin), 293
- Spinal arthropathies (Mitchell), 323
- Spinal canal: sarcoma in (Nordenström and Key), 85
- Spinal cord: lesion of, with atrophy of theanar eminence (Prevost and David), 276; in a case of talipes equinus (Déjérine), 354; compression of, from fracture (Clark), 447
- Spinal symptoms: imperfectly recognised combination of (Erb), 488
- Spine: fracture of (Clark), 447; curvature of (Sayre), 610; connection between auricles in cases of (Perreymond), 668
- Spiroscope, 379
- Splanchnic nerves: arrest of intestinal movements by irritation of (Von Basch), 243
- Spleen: enlargement of (Birch-Hirschfeld), 7; function of (Tarchanoff), 34; cyst of, mistaken for ovarian tumour (O'Malley), 121; modification of blood in passage through (Malassez and Picard), 194; white corpuscles of blood of (Tarchanoff), 477
- Splints: hemp and gypsum (Beely), 262; plaster of Paris (Wackerhagen), 678
- Stammering: treatment of, 28
- Staphylophary: operation of (Prince), 130
- Starchy food: for infants (Korowin), 344
- State Medicine: University of Cambridge examination, 652
- Sterility: from disease of sexual organs (Von Grunewaldt), 27
- Sternum: and ribs, resection of (Mazzoni), 310
- Stethoscope: Arnold's, 648
- Stomach: perforating ulcer of, gastro-pulmonary fistula from (Juliusberger), 37; cases of disease of (Legg), 84, 85; cancer of (Bull and Hansen), 134; prickle-cells in (Schultze), 616; movement and functions of (Leven), 695
- Strawberries: death from eating (Garnier), 408
- Strophulus: treatment of (Hebra), 690
- Strychnia: hydrate of chloral an antidote to (Will and Charteris), 266; in diphtheritic paralysis (Henoch), 271; antagonism of bromide of camphor to (Valenti y Vivo), 374; eating of, as an antidote to alcoholism (Morey), 391
- Succession-sound: in abdominal tumours (Laboulbène), 659
- Sugar: modification of Trommer's test for (Fowler), 105; in normal bile (Naunyn), 197; in fetus and adult (Moriggia), 521; reducing action of (Seegar), 521

The London Medical Record.

WEDNESDAY, JANUARY 6, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ROCHARD ON SURGICAL THERMOMETRY.

M. Rochard (*Histoire de la Chirurgie Française du XIXe Siècle*, Baillière, Paris) discusses shortly the history of medical thermometry according to Wunderlich, and the bibliographical indications of the article 'Chaleur' in the *Dictionnaire de Médecine et de Chirurgie Pratiques*, vol. vi. He summarises the monographs of Galliot,* Demarquay,† Dumeril,‡ Demarquay,§ Verneuil and Billroth,|| and briefly indicates their interesting results.

Traumatic Lesions.—Extensive wounds from surgical operation are immediately followed by a notable elevation of temperature (Simon, E. Montgomery, Demarquay). Galliot observed an elevation of the thermometer to 101° immediately after an accident, followed by subsidence in three days to the normal temperature. In complicated fractures the defervescence is slower; profound concussion of the nervous system produces a similar elevation; serious injuries from shells and fire-arms produced on the contrary depression of temperature varying from 1° to 5°; it is most marked in the subjects of alcoholism. According to Demarquay, whose observations were numerous during the siege of Paris, depression to 95° was always followed by death; this depression seemed to be associated with lesion of the peritoneum. Similar phenomena accompany severe and extensive fevers. (Kuss, Demarquay, Billroth.)

Secondary Accidents of Wounds.—These are always accompanied by an elevation of temperature. Traumatic fever (Billroth, *loc. cit.*) occurs generally in the first seventy-four hours, is accompanied by

rapid rise of temperature, of which the maximum is usually found between the third and sixth day. It very rarely rises above 104°, its *acme* is short; and towards the evening, defervescence is sometimes rapid, sometimes slow, and then accompanied by evening elevations. The prolongation of the *acme* or the return of marked exacerbations are indications of internal inflammation, or of the approach of pyæmia.

Erysipelas has the most characteristic graphic trace; brusque ascensions, uniform and prolonged *acme*, sudden defervescence. The thermometer, after standing at 104° for three or four days, suddenly falls to 98°. This series of events occurs with each outbreak, and this typical course would alone suffice to distinguish erysipelas from purulent infection. In the latter, although the rise is as rapid, and the *acme* reached often higher by two or three degrees, it is extremely short, and the defervescence is rapid; then follows a new access, which goes through the same phases and is followed by several others. The thermographic trace shows alternately very high and very low levels; finally, in the forty-eight hours preceding death, the remissions cease and the thermometer gradually rises to 107°. All these characters suffice to distinguish pyæmia from suppurative and hectic fever, in which there are also exacerbations, but daily, regular, and of minor degree.

The thermometer attains its maximum in tetanus. The remarkable symptom in this disease is the occurrence of a sudden elevation (Billroth, Leyden) in a very few minutes, to excessive temperature, 109° and 111°. This is especially seen in the last period of tetanus, when the diaphragm is paralysed and asphyxia commences. The temperature often rises several tenths of a degree after death. There is no anatomical lesion to explain this fact. [The author does not seem to be aware of the interesting pathological conditions discovered by Lockhart Clarke in the spinal cord, which may well have a direct relation to the elevation of temperature.] In wounds of the spinal cord, almost as considerable an elevation has been observed by Brodie in 1837, Billroth in 1862, Weber (of London) in 1868, Quincke and Fischer in 1869; they have all seen the thermometer rise as high as 107°, and Weber to 111°.

Alterations in the Blood.—All diseases which slowly obstruct circulation, or hæmotosis, are accompanied by a slow depression of temperature, which seldom exceeds from one to two degrees, and is observed at all hours of the day. The same phenomenon is produced in blood-poisoning when it diminishes oxydation, especially in alcoholism and uræmia; in the latter affection the depression is constant and pathognomonic. The thermometer falls sometimes to 86°, and in that case death is at hand.

Local Temperature.—Arterial aneurisms produce appreciable rise of temperature in the affected limb, most pronounced at a distance from the seat of the aneurism; in a case of popliteal aneurism (Brochart*) the elevation on the diseased side in the bend of the knee was only 1.4°, whilst between the toes it was 6°. Demarquay, Monneret, and Henry of Nantes have made the same observation.

When circulation is suddenly arrested by ligature, the temperature below the point of obstruction falls; if circulation is re-established by an anastomosis at

* *Bulletin de la Société de Chirurgie*, 2^{de} série, t. ii. p. 345.

affect the Jews of any country. And, according to Fracastor, the Jews escaped completely the epidemic typhus of 1505. Dr. Stallard, in his work on 'London Pauperism,' says Jewish children have no hereditary syphilis, and scarcely any scrofula. Their greater tenacity of life is, therefore, not only due to better maternal care and nursing, but to the inheritance of a better physical constitution than the Christian child.

M. Lévy estimates that the mean average duration of life among Jews exceeds that among Christians by about five years. In 1849, Prussia computed one death for :—

Evangelists.	Catholics.	Jews.
34·35 inhab.	30·18 inhab.	40·69 inhab.

According to Stallard, the mortality among Jewish children in London from one to five years of age is only 10 per cent., while among the Christians it is 14 per cent. The average duration of life of the Christian in London is thirty-seven years; of the Jew forty-nine years.

In Prussia the Jewish population (1822–1840) increased 34½ per cent.; Christians only 28 per cent. There was one birth to every twenty-eight Jews, one to every twenty-five Christians; one marriage among every 139 Jews, one among 112 Christians; one death among forty Jews, one in thirty-four Christians.

Increase in population among 100,000 individuals :—

	Christians.	Jews.
Marriages	893	719
Births	4,001	3,546
Deaths (still-births included)	2,961	2,161
Excess of births over deaths	1,040	1,385

Legoyt says that the Jews have fewer still-births than Christians. Glätter gives one still-birth in nineteen among Christians, and one in thirty-four among Jews :—

	Christians.	Jews.
Still-born in Prussia in 100,000 inhabitants	143	89
„ „ among 100,000 children	3,569	2,524

According to Lévy, they lose fewer children than other religionists; from 1859 to 1861, we find in Prussia for 100 births the proportions of mortality which follow :—

Evangel's.	Cath.	Philipos.	Ger. Cath.	Mennon's	Jews.
66·37	65·94	56·04	56·77	86·66	48·11

Some of the causes of Jewish longevity are chiefly as follows. They are obliged to keep two Sundays in a week, besides Jewish, Christian, and political holidays. The circumstance of two out of every seven days being lost to business, gives them by necessity about twice as many days of leisure as Christians. They do not engage in mining, mechanics, and other hazardous occupations. The biblical and traditional prohibitions of certain aliments is favourable to longevity. The fifth and last of the summary of causes to which M. Legoyt attributes the greater mean average duration of life of this people, is that 'the *sentiment de la famille*, more developed in them than in Christians, assures to their children, to their aged and infirm parents, a solicitude more active; to the new-born the mother's nursing; to the poor an assistance more efficacious. Their charity is unequalled; their morality is demonstrated by judiciary statistics; the firmness and serenity of spirit are the most marked traits of their character, and proceed from a profound faith, from an unalterable confidence

in Providence.' They rarely use alcoholic liquors, and almost never to excess; this is universally conceded. They seldom marry out of their own race, and have little hereditary disease.

Parton, who quotes from the organ of the London Society for the Conversion of Jews, which spends 250,000 dollars annually 'in converting (?) a few poverty-stricken wretches, and sending abroad on highly interesting tours a few plausible renegades,' confesses :—'As to their moral qualities, the evidence seems to show that the lower class of Jews are decidedly superior to the same class among ourselves. They are far less given to drinking; their religious customs enforce a certain amount of cleanliness, both personal and in their dwellings; and two families are never found inhabiting the same apartment.'

Among the conditions unfavourable to longevity, we may mention their almost universal habit of residence in large cities; and the rarity of their engagement in agricultural pursuits.

Dr. Glätter concludes from all this that, under the relation of duration of life, the Jews are in a condition much more advantageous than Christians. In effect, the more the mean duration of life augments in a people, as is the case with the Jews, the more it diminishes the number of widows and orphans; the more numerous the active and productive class, the more it diminishes the class of pure consumers.

It is evident from all we have here shown, that the numerical increase of a race depends more on the conservation of those already born, than in a great fecundity with less conservation of the issue.

The Jews have always taken every precaution to preserve the life of every individual born.

The Mosaic laws prescribe most of these measures—even to the construction of their houses, requiring balustrades about the roofs to keep children from falling from them. Ancient Rome, with all the jealous care she exercised in the conservation of her citizens, did not approach the excellence of the Mosaic dispensation in these matters.

Jewish subjects would, therefore, appear to be much more advantageous risks for life-companies than other races.

HITZIG ON EXPERIMENTS ON THE BRAIN.

Hitzig, in a new series of experiments ('Untersuchungen über das Gehirn,' Neue Folge, Besonderer Abdruck aus *Reichert's und Du Bois-Reymond's Archiv*, 1874, Heft 4, pp. 392–441), has studied the effects of localised lesions in the brains of dogs. The method consisted in scooping off the grey matter of the cortex to a variable extent from certain regions which had already been experimented on by the galvanic stimulus. The regions operated on directly were in the frontal region, and are classified under two groups. The first group consists of five experiments on the gyri, denominated *a, b, c* (Fig. in text), [corresponding to the frontal portion of the hemisphere in advance of what the Reporter speaks of as the sigmoid gyrus, marked 23 in Fig. 6, *West Riding Reports*, vol. iii., p. 48]. The result of destructive lesions in this region on the left side caused no appreciable symptoms, and especially none as regards motor power. This same region yielded no results on galvanic stimulation.

The second group comprises nine experiments, in which the lesion was directly established in gyrus *d* (Fig. in text) [*i.e.* the anterior division of the sigmoid

gyrus in advance of the crucial sulcus, marked with the letters 3, 4, *op. cit.—Rep.*], but which in some of the experiments extended sooner or later across the crucial sulcus, and affected the regions stimulation of which causes movements of the legs. Stimulation of this special region yielded to Hitzig either negative or very indefinite results. From an analysis of these cases Hitzig concludes, that 'the question whether gyrus *d* stands directly or indirectly in relation to muscular movement or not, is answered in the negative, and that the irritation experiments are confirmed.' In the other cases where affections of motion in the limbs were observed, which Hitzig describes as 'disturbances of muscle-consciousness' (Störungen des Muskelbewusstseins), gyrus *e* (*i.e.* the posterior division of the sigmoid gyrus (*Rep.*) was found to be more or less involved in the lesion. Another symptom which he describes as occurring with this 'Störung des Muskelbewusstseins,' is a defect of the energy of the will ('Defect der Willensenergie'), which symptom also resulted in two cases from lesion of gyrus *d*. He also remarks that extensive lesions of the posterior regions of the brain have a similar effect, but not to the same extent as limited lesions in gyrus *e*. Another point to which he calls attention is, that the limbs of the animals in which gyrus *e* was destroyed, in addition to the aimless and defective co-ordination of their movements, exhibited a different relation to each other and to the trunk when the animals were raised up. The limb was placed irregularly on the ground, the animal frequently fell, and was unable to maintain its foothold, though the limbs were placed in the proper position to support the body. The cause of this peculiarity, and its relation to a similar symptom described by Nothnagel in rabbits, Hitzig is unable to decide.

As the most remarkable phenomenon in his experiments, he characterises the results obtained in one dog, in which both gyri *d* and *e* were destroyed. This animal was affected with well marked disturbance of its 'Muskelbewusstsein,' but had not lost its sight, yet it moved its fore-paw as if it did not see, or as if it could form no conception of its position. This and other facts Hitzig promises to consider more minutely hereafter.

[Without wishing to anticipate a more minute examination of these and other experiments of Hitzig on the functions of the cortical centres, the Reporter would merely indicate that his interpretation of these and similar experiments, now as before, differs from that of Hitzig in vital and fundamental respects.—*Rep.*]

D. FERRIER, M.D.

ANATOMY AND PHYSIOLOGY.

BEQUEREL ON THE INTERVENTION OF PHYSICO-CHEMICAL FORCES IN THE PHENOMENA OF LIFE. The study of these forces, in life, the author says (*Comptes Rendus*, December 7) presents many difficulties; and in a memoir presented to the Academy (here abstracted), he approaches it from a consideration of the nature of the active forces and their mode of action, apart from that of the products formed.

Of physico-chemical forces influencing organic functions, perhaps the most important are the electro-capillary. These, consisting of electro-capil-

lary currents, only require, for their production, permeable tissues separating two different liquids; a frequent case in the animal system.

It is easy to prove their existence and direction with a galvanometer. Their intensity can be measured by the method of opposition, which consists in opposing to the current whose intensity is sought, another current from a certain number of thermo-electric couples united in a pile, till the galvanometer is no longer deflected; the number of couples employed represents the intensity of the current.

The question treated in the present memoir is that of currents produced on contact of the two bloods, and of different liquids in the system, separated only by tissues; also on contact with other liquids. [In no. xxxvi. of the Academy *Mémoires*, the author has studied electro-capillary currents in the muscles, the bones, and the brain.]

He begins by giving a rapid description of the mode of translation of blood in the vessels, in order to point out how numerous currents must arise in this translation. Arterial blood, before becoming venous, passes through capillary vessels, where it is in contact with muscles covered with exuded liquids; this contact gives rise to electro-capillary actions which concur in their nutrition and increase, evolving certain elements, particularly carbonic acid, which is carried into the lungs by the blood become venous; the arterial blood, then, continually undergoes profound changes, and is charged with carbonic acid in the lungs.

We may thus see, that the electro-motive force, direction, and intensity, produced on contact of arterial with venous blood, has not major importance, since the arterial blood becomes successively venous blood; this force is to be considered as the resultant of electro-motive forces produced in the course of the two bloods.

This is how M. Becquerel, assisted by M. Dastre, sought to measure the electro-motive force in a chloroformed dog.

The carotid and jugular are laid bare on one side, and a T-tube, inverted, is introduced into each vessel (the blood having been stopped in a certain length of the vein or artery, by means of ligatures, and two incisions made, the two tapering ends of the glass tube are inserted in these, and the vessel tightly tied about them with a waxed thread); the other branch of the tube is connected with a caoutchouc tube; an electrode, formed of a thin plate of platinum, rolled in a spiral and carefully depolarised, having been inserted in the vertical branch of each tube, the blood is again allowed to pass; the two electrodes are connected with a galvanometer, and the method of opposition brought into service.

In three such experiments, the following electro-motive forces were obtained (referred to those of a cadmium couple valued at 100.)

Electromotive forces.

Blood of carotid artery . . . - }	21-22 . 33-43 . 28-32½
„ jugular vein . . . + }	

(The arterial blood is negative instead of positive, as M. Scoutteten has affirmed; but in his experiments the polarisation of the plates seems to have been a source of error.) The differences arise from the difficulty of operating in the same conditions, when the artery and vein continue open some time. One may avoid, in part, these changes, by operating with two defibrinated portions of blood, one of which is introduced into a cracked tube, immersed in a

vessel containing the other; the electromotive forces are then less, and present less differences, as the following shows.

		Electromotive forces.
Arterial blood	: +	10-8. 8-10 (average g).
Venous "	: -	

It is seen that the electric effects are here inverse to those obtained previously.

Not being able to bring each of the two bloods directly into contact with the liquid exuded from the muscles, M. Becquerel operated as follows on the live animal. Each of the two blood-vessels was placed successively in a small gutter of glass, containing (first) distilled water; then the platinum plates, thoroughly depolarised, were immersed, one in the water, the other in the arterial or venous blood. In this way a force of 67 was observed in the case of arterial blood (-) and water (+); and a force of 47 with venous blood (-) and water (+); difference 20.

Operating with defibrinated blood, on the other hand, the corresponding differences, in three experiments, were 10, 12, 10, though the forces varied from 39 to 49, with arterial blood (-) and water (+) and from 49 to 70 with venous blood (-) and water (+).

A series of similar experiments were made, in which the water was replaced by various other liquids, as bile, urine, wine, grape-juice, sugared water, and water charged with carbonic acid. It was always observed that the blood was negative to the other liquid, whence we may infer the same to occur on contact of arterial blood of the capillaries with the liquid exuded from muscles. The direction of the electro-capillary currents is such, that the interior walls of the capillaries are the positive electrodes of couples acting as chemical forces, and the exterior walls the negative electrodes. There is, then, oxidation within the capillaries, and reduction on the side of the muscles.

It has been found that the interior of a muscle is negative, in general, to the liquids which moisten the exterior part; the electro-capillary currents go, then, from the interior to the exterior; consequently, there is oxidation within and reduction without. We may thus see what a multitude of various chemical reactions take place in the interior of organised bodies.

The same mode of experimentation has been used in observing electro-capillary currents in fruits, etc., the apple, the pear, the potato, the carrot, and the turnip; on contact with water, it was always found that the interior part was positive. Thus, when fruits are wet (with fresh water), their internal parts near the external tissue continually tend to be oxidised (salt water produces contrary effects).

Before we knew of electro-capillary currents, it might have been supposed that, on sending an electric current into an organised body, in therapeutic treatment with electricity, electro-chemical actions were not produced, that is, effects of composition and decomposition; inasmuch as there were not solid bodies present, conductors of electricity, and capable of serving as electrodes (as happens when a metallic wire is introduced into a solution traversed by an electric current); but since it is known that the extremely thin liquid layer adhering to the walls of tissues permeable by capillary action behaves like a metallic plate in electro-chemical decompositions, we can perceive how these phenomena may equally be produced in the system.

And such effects must therefore be taken into consideration in therapeutical applications of electricity; for, according to the direction of the battery current, the electro-capillary current tends to oxidise or to reduce the blood, and contrary effects are produced on liquids adherent to the walls; thus extremely complex chemical effects may result, the study of which is very difficult.

GRUBER ON THE FRONTAL FONTANELLE-BONE.—OS FONTICULI FRONTALIS.—Out of the enormous collection, numbering about 10,000 human skulls, amassed in the comparatively short space of a quarter of a century in the Institute of Anatomy at St. Petersburg, Professor Wenzel Gruber found forty-three to possess a 'Wormian bone' lodged in the former site of the anterior or frontal fontanelle. His observations and notes are comprehended in a paper published in the *Mémoires de l'Académie des Sciences de St. Petersburg*, tome xix., entitled, 'Ueber den Stirnfontanellknöchen (os fonticuli frontalis) bei dem Menschen und bei den Säugethieren,' and illustrated by two plates of fifty-seven figures. Of the forty-three skulls the fontanelle-bone was single in forty, double in one, and triple in a hydrocephalic boy, in whom there were about thirty 'Wormian' bones besides, lodged in the lambdoidal suture. It follows that very rarely—viz., only once in every 250 skulls—is a specimen met with having a fontanelle-bone. The bone itself is generally of an irregularly rhomboidal shape, and is imbedded between the frontal and two parietal bones, in such wise that its anterior angle or margin enters into the formation of a part of the coronal suture. Complete synostosis of the bone with its three neighbours occurred in no case externally, while internally it was seen in twelve out of the forty having but a single fontanelle-bone—and out of these there was not a trace of a suture in seven—and also in the skull with a double Wormian bone in the site of the anterior fontanelle. In anatomical literature, about from eighty to ninety cases are registered, in which the bone in question was present, and only one case—quoted by Meckel (*Handbuch der pathologischen Anatomie*, Band i., Leipzig, 1812), in which it was double. Very little is deducible from observations made upon lower mammals (including from thirty to thirty-two species of twenty-five to twenty-seven genera out of nine orders observed), except that, as in well-formed human skulls, so in well-developed skulls of other mammalia, the triple as well as the double and single varieties of the bone may be present; and, as in man, the single variety the oftenest. It must be noted that in one and the same species of mammals the multiple variety may be oftener present than in man. To judge from Professor Gruber's notes, the abnormal ossicle seems to be more frequent among the Edentata—occurring in both kinds of sloths—than in the rest of the mammalia.

J. C. GALTON.

MORIGGIA ON DIGESTIVE FLUID IN THE FÆTUS. A. Moriggia (*Revista Clinica*, 1873; abstract in *Centralblatt für die Medicinischen Wissenschaften*, no. 22, 1874) has investigated more than a hundred embryos (chiefly of the cow), from the most different periods of development, and has found that the digestive power of the mucous membrane of the stomach is present, and can be demonstrated, not only in the sixth and fifth, but also in the fourth and third months of pregnancy. The salivary glands, on

the contrary, have no digestive properties either in the fœtus or in the newly born. (Compare Schiffer and Korowin, *Journal of Anat. and Phys.*, vol. viii.) The bile-forming function of the liver begins very early. When the liver begins to produce glycogen could not be accurately ascertained; for, even at the earliest period of development of the liver, almost all the embryonal tissues contain glycogen or glycose. Embryos which have been preserved for a long time at the temperature of the body, in Moleschott's acetic acid mixture, were by the action of their own gastric juice completely digested, without a trace of them being left. To self-digestion the author seeks to ascribe the disappearance of dead embryos in closed cysts. The parts of such embryos which generally remain to the last are either those which are widely removed from the stomach (*e.g.* head), or those which afford resistance to the digestive power of the gastric juice (*e.g.* hair, bones). From the constant presence of amniotic fluid in the stomach, and of amniotic epithelium in the meconium of the embryo of the cow, it is to be concluded that a constant swallowing of the amniotic fluid takes place in the embryo.

GRÜTZNER ON A NEW METHOD OF ESTIMATING THE QUANTITY OF PEPSIN BY THE COLOUR.—P. Grützner describes this method in *Pflüger's Archiv*, vol. viii. (abstract in *Centralblatt für die Medicin. Wissenschaften*, no. 20, 1874). Fibrin is to be coloured by placing it in a solution of carmine, then immediately preserved in glycerine, and before making an experiment, after washing away the glycerine, it is placed in dilute hydrochloric acid (two per cent.) until it swells up. By this means a beautiful red coloured jelly-like mass is obtained, which is easily dissolved in digesting fluid, and just in the degree to which it dissolves it is coloured red. The greater the quantity of pepsin in the fluid to be investigated, the quicker does the solution of fibrin take place (*ceteris paribus*), and therewith the red colouring of the fluid. This method is as equally well fitted for the detection of small quantities of pepsin, as for the comparison of the quantity of pepsin in two fluids.

PATHOLOGY.

HILLER ON THE ERYSIPELATOUS INFLAMMATION-PROCESS.—Dr. Arnold Hiller, of Berlin (*Berliner Klinische Wochenschrift*, nos. 48, 49, 1874), gives an elaborate article on the pathology of erysipelas, the specific peculiarities of which inflammatory affection are its infectious character, its tendency to affect only superficial parts and to spread continuously, and, finally, its extremely slight tendency to suppuration and formation of abscess, notwithstanding the prolonged presence of perfect and undoubted inflammatory phenomena. This last established characteristic is of the greatest interest theoretically, as it contradicts the modern pathological doctrine based on experimentation and observation, that every

form of regularly induced inflammation—and as such is erysipelas to be considered—is associated with the migration of white cells. This peculiarity of erysipelatoous inflammation is due not to any anatomical peculiarity of the affected organ, but to the specificity of the cause of the inflammation. The tendency of modern pathologists to attribute to erysipelas, as to other infectious morbid processes, a parasitic origin, and an extension by means of very low organisms (bacteria, micrococci), is opposed by the author, who points out as objections to it the facts of the ubiquity of these organisms, of the frequent opportunities for their introduction into the body, and of the organic uniformity of the objects as contrasted with the multiplicity of morbid processes to which they are supposed to give rise. Hiller repeats here some critical observations on a paper by Lukomsky (*Virchow's Archiv*, Band lx.), in which this view of the parasitic origin of erysipelas was supposed to be proved by anatomical and experimental data. In the first place, Hiller expresses his doubt as to whether the bodies found by Lukomsky in cases of erysipelas were really micrococci, and states that the strongly light-refracting property, the bright lustre, and the sharp contours of these bodies, together with their resistance to the action of acetic acid, indicate a fatty nature. Bacteria have but little lustre, and present a feeble and indistinct contour. Masses of these bodies were found by Lukomsky in five only out of nine cases of erysipelas, and these only at the margins of the inflamed part, the centre of the disease and the starting-point of the infection being quite free from them, a fact in direct opposition to what is known concerning the vegetation and local extension of bacteria, and to the results of pathological experiments on animals. This absence of the supposed micrococci from the central portions of the inflamed part cannot properly be explained, Hiller holds, by the idea of absorption or migration. The bodies observed by Lukomsky, on the other hand, formed large masses, completely filling the lumen of vessels, and, for mechanical reasons, could not be absorbed; and, on the other hand, they are stated to be quiescent bodies without any capacity for active locomotion. The supposed property of these bodies of setting up inflammation is disproved by the fact, that in all those portions of tissue which present under the microscope the most marked inflammatory changes, very few, if any, collections of the so-called 'micrococci' are to be found; whilst at parts where lymph, and blood-vessels, and capillaries are filled with them, no trace of any cellular infiltration of the tissue is visible. Lukomsky succeeded in setting up fatal spreading inflammation in rabbits by injecting putrid, and therefore bacteria-containing fluids; but as many believe in a chemical action of the septic substance that excites erysipelas, Hiller holds that the experimental side of the question cannot be settled until inoculations are made, firstly, of putrid fluids deprived of all organisms by filtration, and secondly, of a chemically indifferent fluid containing organisms unmixed with chemical material. Hiller holds that both experimentation and clinical experience demonstrate the chemical nature of the poison of erysipelas, and that this poison is formed by the decomposition of organic substances rich in albumen (wound secretion). It is, therefore, highly improbable that the poison of erysipelas is a specific one. As a rule, all septic poisons work in a like manner; locally they are intensely phlogogenous,

generally they are actively pyrogenous, with certain associated toxical phenomena dependent on the intensity of the blood-poisoning. That its absorption from the wound leads in one case to lymphangitis, in another case to erysipelas or ichorous phlegmon, in other cases again to septic thrombo-phlebitis with embolia (pyæmia), or to pure septicaemia, seems to Hiller to depend not on a specific mode of action of this or that material, but rather on the tracts of absorption, the locality in which it acts, and in the mode and rapidity of its spreading. Again, the possible variations in the progress of any one of these forms of infection depend on the one hand on the amount, the intensity, and the concentration of the poison, and on the other hand on the multiplicity and casual combination of those various septic products of decomposition, each of which may possibly have a special poisonous action. According to Hiller, this specific poison of erysipelas enters either by the lymph-vessels and capillaries of the skin and subcutaneous connective tissue, or by the veins; in the former instance acting slowly and with pyrogenous results, in the latter instance speedily and with phlogogenous results. The entrance of the poison is indicated by signs; but when the second form of infection occurs, local inflammatory signs may be observed before shivering and elevation of temperature. In addition to the common local changes found in inflamed structures, such as vascular dilatation and distension, retardation of blood-current, increase in the number of white-cells, etc., Hiller describes certain peculiar changes which he observed in advanced stages of erysipelas. The serum of the blood becomes altered, the red corpuscles become wrinkled and disorganised, and the white corpuscles undergo necrobiosis and, in some instances, necrosis. The blood contains an increased number of the white corpuscles, which are very granular and filled with small bright molecules; with the further action of the poison the corpuscles lose their contour, and are converted into more or less spherical heaps of strongly refracting molecules. It was supposed at first, that these masses of molecules were formed by a process of fatty metamorphosis of the contents of the white corpuscles; but Hiller is now inclined to regard them as the products of inflammatory proliferation of the nuclei of the corpuscles. Associated with these nutritive changes of the white or lymph corpuscles there are important functional changes indicated by arrest of the amœboid motility and contractility of these bodies, in consequence of which their migration is retarded, and often altogether prevented; this Hiller regards as the main peculiarity of the erysipelatous inflammatory process, and the reason why it seldom results in suppuration and formation of pustules or abscesses. The *restitutio ad integrum* of the tissues affected by erysipelas is dependent on the rapidity of the removal of the stagnant masses of detritus formed by the degenerated corpuscles. This, in ordinary and favourable cases, takes place by absorption, by which term is indicated the mechanical soaking of the degenerated corpuscular elements in the incubating fluids. When this absorption does not take place, inflammation persists and becomes more intense, and fresh masses of detritus are formed, under the influence of which, added to the direct action of septic poison pervading the affected tissues, local death is produced (erysipelas gangrenosum). In phlegmonous erysipelas, where there is a tendency to suppuration, and usually a termination in the formation of an abscess, the

phlogistic action of the septic poison is more marked than its necrotic and specifically toxical action on the lymph-corpuscles and the blood. Septic poisons which act thus are formed in advanced stages of putrid decomposition, and this form of erysipelas somewhat corresponds to the phlegmonous inflammation of the integument that can be produced experimentally by the injection of putrid fluid. Hiller thinks that, from a pathological stand-point, it would be well to strike out this from the recognised forms of erysipelas. In conclusion, Hiller states that erysipelas does not attack the skin only, but that in his opinion every inflammation which is of infectious origin, and which creeps slowly over the surface of any organ without causing suppuration, is to be regarded as of erysipelatous nature. Such erysipelatous inflammation is met with in the inflated puerperal uterus, and in several forms of angina marked locally by swelling and redness of the mucous membrane of the mouth, fauces, and pharynx, and constitutionally by the occurrence of rigors and subsequent high fever.

W. JOHNSON SMITH.

BIRCH-HIRSCHFELD ON ENLARGEMENT OF THE SPLEEN, ESPECIALLY IN INFECTIOUS DISEASES.—At the forty-seventh congress of German naturalists and medical men, lately held at Breslau (*Berliner Klinische Wochenschrift*, November 30, 1874), Dr. Birch-Hirschfeld, of Dresden, remarked that formerly attention had been directed to enlargement of the spleen in malarious diseases, and in enteric fever, but not in other maladies. Of late it has become more and more evident that acute tumefaction of the spleen occurs in a number of infectious diseases, as, for example, in relapsing fever, and, as pointed out by Weil, in recent attacks of syphilis. Friedreich has even proposed to utilise the splenic tumour as a means of establishing the infectious nature of certain diseases hitherto considered as simple local affections [many forms of pneumonia, coryza, angina, etc.] The speaker had already brought before the Leipzig Natural History Society experiments on the behaviour of the cells of the splenic pulp with finely divided substances introduced into the blood-mass. Since then he had endeavoured, with the anatomical and pathological materials at his command, which were somewhat extensive, to furnish some foundation for the statistics of splenic tumours. Clinical observations by themselves are not always trustworthy, because even experienced observers may easily make mistakes as to the percussion-limits of the spleen. In order to judge of the dimensions of the normal spleen, the bodies of sixty persons, who were suicides, or who met with violent deaths, but were otherwise healthy, were taken as standards. The average weight of the spleen was 150 grammes ($4\frac{3}{4}$ ounces nearly), equal to 0.26 per cent. of the body weight. In 145 other cases, under fifty years of age, the result was not very different, namely 140 grammes ($4\frac{1}{2}$ ounces or 0.27 per cent. (*sic*). Above sixty years, the weight of the spleen, like that of the body, decreases considerably, being 99 grammes ($3\frac{1}{2}$ jss), or 0.23 per cent. of the body weight. Birch-Hirschfeld distinguishes between the etiology of primary cases of enlarged spleen (in leucæmia, and in bodies appearing otherwise healthy, dependent upon hypertrophy of the pulp and Malpighian corpuscles), and secondary cases. To the latter belong (a) splenic tumours dependent on blood-stasis (considerable enlargement from uncompensated mitral insufficiency; spleens a little

above normal in insufficiency of the aortic valves; finally, the pretty constantly occurring enlargement accompanying cirrhosis of the liver); (b) splenic tumours through amyloid degeneration; (c) those which occur in infectious diseases. In enteric fever the spleen-tumour is generally most marked in the second or third week, and disappears in the fifth week. He confirms Friedreich's observation, that the spleen is enlarged during the period of incubation. In the common form of variola, when fatal, there is no enlargement of the spleen. He includes the splenic tumours found in some forms of pulmonary tuberculosis amongst those caused by septic infection; the tumefaction of the spleen occurs in cases where the walls of cavities afford a surface favourable to absorption, especially where sudden ulcerative breaking up of the lung is brought about by purulent bronchitis. Comparison of metastatic pyæmia in the wounded and in puerperal cases, and of phlegmonous and gangrenous diseases of wounds without metastatic formations, with the phlegmonous simple peritonitic form of puerperal fever, showed this analogy, that the rule is to find a splenic tumour where there is metastatic infarction, or where infectious thrombi can be demonstrated in the course of the circulation; but where only phlegmonous processes are discoverable, the splenic tumour is hardly ever found. If we admit that there is a common source of infection for both forms, we must conclude that the matter absorbed by the splenic pulp-cells must be a non-diffusible one of stable constitution. Granular degeneration, along with solution and increased multiplication of the splenic pulp-cells, is peculiar to the septic tumours of the spleen, whilst, in enteric fever, the latter changes predominate. The septic tumours of the spleen appear to the naked eye as very soft, and of a pale yellowish-red, or speckled aspect. In congenital lues, enlargement of the spleen is almost always discoverable. In four cases also of acute rheumatism ending fatally, and in six of scarlatina, the spleen was found much enlarged.

W. BATHURST WOODMAN, M.D.

MEDICINE.

PINCUS ON THE TREATMENT OF TAPEWORM.—At a meeting of the Berlin Medical Society held on October 28, 1874 (*Berliner Klinische Wochenschrift*, November 30), Herr Pincus remarked that many medical men consider a preparatory treatment necessary before administering anthelmintics. This preparation consists of oils and low diet for some days beforehand, or of two or three days physicking, which irritates the worms. The consequence, he states, is that when the anthelmintic is given, portions only of the body, and not the head, are expelled. The remedies may be divided into two classes, namely, those which paralyse the movements of the proglottides, koussou, panna [the rhizome of *Lastrea* (*Aspidium*) athamanticum, much esteemed by the Zulu Caffres, and somewhat resembling our male-fern], kameela; and those which act upon the organs of adhesion, as the bark of pomegranate-root and male-fern. Whichever be employed, the best result is obtained by giving a full dose without any preparatory medication. Again, it has been advised, when the worm is found to protrude from the anus, to do nothing except let the patient sit over warm water; this may be done for hours, and the only

consequence is, that after from eight to ten feet of worm have come away, there is no further progress; probably because the head is not paralysed, and remains adherent, whilst the proglottides come away. In such cases Dr. Pincus gives a narcotic clyster, if the movements of the worm be lively; and then, in less than an hour, even when the tapeworm is broken, he has found the head to come away. The older remedies, such as pomegranate-root bark, are preferable, because they do not much derange the patient's health. Professor Henoch remarked that narcotic clysters, even with chloroform, had been recommended some time since. He asked if Dr. Pincus had himself experimented upon the worms. Dr. Pincus said that he meant substances which narcotised the worms themselves, particularly pomegranate-root bark. He had made experiments upon the proglottides passed by patients; the movements of these ceased immediately when subjected to koussou, panna, or kameela. He had made no direct experiments on the action of the other remedies in paralysing the adhesive organs. Professor Liebreich drew attention to the koussine or koussein prepared by Bedal, of Munich, which was not an alkaloid, but contained the resin of koussou. Two grammes of this preparation have the same effect as twenty grammes of koussou [35s koussine is equal to 3v of koussou.] Herr Paasch had also used pomegranate-root bark, but considered no cure as complete unless the worm came away *suâ sponte*. Professor Henoch denied that the passing of proglottides denoted the worms being themselves out of health; the proglottides severed themselves when sexually ripe, in order to pursue their farther transigrations. Herr Fürstenheim mentioned the thick lozenges prescribed by Rosenthal as very convenient in practice. They contained koussou. Herr Pincus believed that the proglottides become separated, when the fibres which connect them are so softened and worn that the alkaline mucus of the bowel dissolves them.

KLINGELHÖFFER ON THE TREATMENT OF MALIGNANT PUSTULE WITH CARBOLIC ACID.—In the *Berliner Klinische Wochenschrift* (no. 44), for November 2, 1874, Dr. Klingelhöffer, of Heusenstamm, gives an account of five cases of malignant pustule observed and treated by him. All the patients were tanners, employed in the same tanyard at Offenbach. The sites of the pustule or charbon were as follows; in no. 1, the angle of the lower jaw; no. 2, the upper lip; no. 3, the side of the neck; no. 4, the upper eyelid; no. 5, the forearm. It is remarkable that only the latter was in a site directly exposed to contagion from the skins or hides. Nos. 1 and 3 were treated by caustic potash locally, and liquor chlori internally. The first recovered, the other died in forty-eight hours. The others, nos. 2, 4, and 5 were treated by the pustules being cauterised, as deeply as possible, by the liquified crystals of carbolic acid; strong solutions (one to eight) in water or linseed oil being kept constantly applied afterwards, and the acid given internally. All three recovered, though none were seen till the second or third day. They were very severe cases. It is noteworthy that neither gave rise to fresh cases, although the last slept with six children and his parents in one room, and in the same bed with a case of acute eczema. Dr. Klingelhöffer recommends a mixture of ten grains of pure carbolic acid in six ounces of water; a tablespoonful being given every two hours. He considers the official doses (0·05 gramme, equal to $\frac{3}{4}$ grain as a dose, and

0.15 gramme, equal to $2\frac{1}{2}$ grains *per diem*) as too small. He has often greatly exceeded this. [The dose of the British Pharmacopœia is one to three grains, and the reporter has never seen bad effects from this, if well diluted. He has frequently given as much as ten grains in the twenty-four hours to adults, in appropriate cases, without any unpleasant effects.—*Ref.*] W. BATHURST WOODMAN, M.D.

SURGERY.

BOZEMAN ON THE PASSAGE OF THE HAND INTO THE RECTUM.—Dr. W. Bozeman, writing in the *New York Medical Record* on a case which he witnessed in Professor Simon's clinic at Heidelberg, says the subject of rectal and vesical explorations, which has attracted much attention in England and America during the last two or three years, was illustrated by Professor Simon upon this patient in the most practical manner. The passage of the hand into the rectum as a means of diagnosis, I believe, originated with him, and, bold and reckless as the procedure may appear to many, it is destined, when better understood, to prove a most valuable means of diagnosis. To be able to pass the hand and arm, per anum, to a point in the abdomen where the left kidney and false ribs can be felt, and the abdominal-wall, of the same side, to the median line, be lifted up, at every point, upon the ends of the fingers, seems almost incredible; and yet I saw this practised by Professor Simon upon his patient. Both Mr. Wells and myself, at the request of the Professor, made the same exploration with a satisfactory result.

From what I have seen and heard of this procedure at the clinic of Professor Simon, I am convinced that the dangers and accidents supposed to attend it have been greatly exaggerated. He says he has met with no difficulty, except now and then a little incontinence of fæces, which, however, continues only two or three days. The preparation for the operation consists in complete anæsthesia and in thoroughly washing out the large bowels. The latter, Professor Simon prefers to do by hydrostatic pressure, using for this purpose a graduated glass cylinder with a faucet near its bottom, and a long India-rubbertube terminating in the ordinary clyster-nozzle. From two to three quarts of water usually suffice. The apparatus is held by an assistant three or four feet above the patient. Dr. Simon has now operated eight times through the anus for recto-vaginal fistula, and he thinks the procedure preferable to the ordinary method where the fistula is situated high up. Why not approach the male bladder in the same manner, in cases of chronic catarrh and ulceration, and of great enlargement of the prostate gland where micturition is attended with difficulty? Cystotomy, under such circumstances, I have long thought to be not only a justifiable procedure, but one likely to be attended with good and encouraging results.

WACKERHEGEN ON A NEW METHOD OF APPLYING PLASTER OF PARIS BANDAGE.—Dr. Wackerhagen writes as follows in the *New York Medical Journal*. As I have experienced considerable difficulty in removing plaster of Paris dressings when applied by the roller bandage, and especially when obliged to remove them on account of pain caused by an increase of the swelling, I respectfully submit to the profession a method of application by which these disadvantages may be avoided. Having procured a woollen or cotton stocking sufficiently long to reach to the knee-joint, I cut from it, as a pattern, six layers of coarse red flannel (one quarter of an inch larger to allow for shrinkage). The flannel is then soaked in water, pressed, and laid over the back of a chair ready for use. A one-quarter-inch cotton rope is now sewed to the posterior median line of the stocking. The plaster of Paris being in process of preparation, the stocking is cut in the anterior median line, applied to the fractured limb, and laced up in front, including the rope, extension and counter-extension being kept up by assistants, and the fracture adjusted. Each layer of the flannel is now saturated in the plaster paste, and applied, three layers to each side of the limb, being careful to avoid covering the rope. After this is done, a layer of plaster paste is applied to the flannel, and, when this has become sufficiently dry, a coating of shellac varnish is applied, which produces an elegant finish, and also gives firmness to the splints. The varnish will dry in about fifteen minutes. This dressing can be removed in from three to five minutes, by loosening the rope from the plaster and cutting the thread which binds it to the stocking. The rope having been removed, the plain stocking surface can be cut through with an ordinary pair of scissors. The splint is then removed in two lateral portions, each half of the stocking remaining attached to its corresponding splint.

PIZZORNO ON THE CURE OF POPLITEAL ANEURISM BY DIGITAL COMPRESSION.—In *Lo Sperimentale* for November, 1874, we have an account by Dr. Pizzorno of a case of popliteal aneurism under the care of Dr. Corradi, successfully treated by digital pressure carried out by relays of assistants (four to the hour) during the space of three days. The points to which the author calls attention in the case are these. 1. The aneurism occurred in a perfectly healthy man about thirty-eight years of age, who had never had syphilis, and who was not aware of having received any injury—the only probable exciting cause being prolonged exposure of the lower extremities to wet, while he was laying the foundations of some houses. 2. The injection of ergotine into the neighbourhood of the tumour entirely relieved the pain caused by the aneurism itself, and, as he believes, much facilitated the treatment; while the pain caused by the compression was not at all relieved by the ergotine, but yielded readily to morphia. 3. The cure by digital pressure was aided and facilitated by pressure made directly on the aneurism with an air-ball bandaged into the ham in the bent position.

T. HOLMES.

INTRAVENOUS INJECTION OF CHLORAL FOR PRODUCING ANÆSTHESIA.—At a late meeting of the Paris Academy of Sciences, M. Oré forwarded particulars of two fresh cases of anæsthesia, produced by the intravenous injection of chloral. In one case the object proposed was to scoop out the tibia on account of caries of the bone, the other

was for the operation of ovariectomy. Anæsthesia in both cases was complete, and was neither accompanied nor followed by any accident which could be attributed to the chloral. M. Oré took the opportunity to point out the means of neutralising the possible acidity of the chloral, a circumstance which might possibly bring on coagulation of the blood in the veins. For this purpose it is sufficient to dissolve one gramme of carbonate of soda in ten grammes of distilled water, and to add two or three drops of this solution to a solution of one gramme of chloral in four of water.

MATERIA MEDICA AND THERAPEUTICS.

BARTHOLOW ON COMBINED ADMINISTRATION OF CHLORAL, MORPHIA, AND ATROPIA.—Dr. Bartholow, in a paper read before the New York Society of Neurology, October 19, began by stating the desirableness of further knowledge of the reactions which ensue when remedies affecting the nervous system are conjointly administered. He had to offer to the society a condensed summary of the results obtained from the simultaneous administration of chloral, atropia, and morphia.

Chloral differs from morphia, when injected subcutaneously, in the more decided systemic effects and the less local impression on the sentient nerves. As regards the systemic effects, the action of chloral is very much the same when administered hypodermically as by the stomach. The chief danger is an arrest of the respiratory movements. Chloral does not exert any chemical action on atropia when the two are held in solution together, for dilatation of the pupil of a cat takes place when the combined solution is instilled into the eye. Dilatation of the pupil also happens when they are administered hypodermically together. An apparent antagonism is observed as regards their action on the heart, when the solutions of chloral and atropia are placed in contact with the heart of a frog when in position in the chest, after division of the medulla, or when the heart is removed. The action of the heart is further found to continue much longer when a lethal dose of chloral is administered together with atropia. In rabbits the same result is produced by the conjoined administration of the two agents.

Atropia is found to prolong the chloral narcosis several hours in rabbits, and diminishes the sensibility to pain. In man the excitant action of atropia hinders the occurrence of the chloral narcosis, but rather deepens the sopor when it at last supervenes. The effects of atropia last much longer, and are, apparently, in no way prevented by chloral.

Morphia deepens in every way the effects of chloral. Dr. Bartholow found, in the course of some

experiments on himself, that many of the unpleasant effects of morphia are modified, as regards the wakefulness caused by the latter, but are not modified as regards the subsequent nausea, vomiting, vertigo, and constipation. When the two agents are administered conjointly, a much less quantity of chloral is necessary in order to produce sleep.

These agents act much more happily when administered simultaneously. Chloral causes sleep, morphia relieves pain, and atropia prevents or lessens the depression in the respiratory and cardiac movements caused by the other two, whilst it contributes to their cerebral effects.

These physiological studies are confirmed by the therapeutical results. The combination of chloral, morphia, and atropia is adapted to those cases of insomnia caused by pain, or in which chloral and morphia alone merely increase the cerebral excitement, as in hypochondria, puerperal mania, etc. This combination is also indicated in cases of fatty and irritable heart.

When pain is to be relieved, chloral is not so serviceable alone as in combination with morphia and atropia. The local administration—that is, the insertion of the medicament at the site of pain—is more effective than the merely systemic impression. This is especially the case in tic douloureux, sciatica, and coccydynia, which are much more effectively treated by injections practised into the neighbourhood of nerves which are the seat of pain. The combination of local irritant and benumber with a systemic anodyne is more curative than either used singly.

In cases of muscular spasm, the author of the paper had obtained excellent results from the combined use of chloral, morphia, and atropia, and he especially called attention to the efficacy of these agents in the cramps of cholera. Many cases of spasmodic asthma and hay-fever had been benefited by their conjoint administration.

DEXTER ON REST IN THE TREATMENT OF CHOREA.—Dr. Ransom Dexter (*Chicago Journal of Nervous and Mental Disease*) reports the case of a girl, aged thirteen, whose health was impaired by hard study at school, and who finally became choreic. The treatment at first adopted consisted in the administration of extract of valerian and cimicifuga twice a day, the elixir of pepsin, bismuth, and strychnia before each meal, and bromide of potassium and cannabis Indica at bedtime. In a few days she grew worse, and some malarial periodicity was noticed. It was then decided to try cautiously small doses of quinine and iron, but when only four grains of the former had been administered the following symptoms ensued: hemiplegia of the left side, dilatation of the pupils of both eyes, some choreic movements during sleep, increasing so much when awake that the patient was unable to sit up, but had to be held down on the bed or lounge. In reviewing the case, which had then become very serious from the general failure of the vital powers, Dr. Dexter arrived at the following conclusions.

1. All the sensorial ganglia, or the centres for the nerves of the separate senses, were more or less affected; and that the sensori-motor centres were the special seat of the disease.
2. The pathological condition could not be other than an asthenic irritation of the sensori-motor organs.
3. These organs must have physiological and therapeutical rest.

Carrying out these ideas, he ordered the patient to be kept in a darkened room; to lie as still as possible upon a lounge; to be waited upon only by her parents, who were to maintain the strictest quietude; and to be positively silent herself. In addition, the valerian, cannabis indica, and bromide were continued, with an occasional cathartic to act as a revulsive. In eight hours a noticeable improvement had ensued, and in twenty-four hours had become very decided. In six days all choreic movements had disappeared.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT (BROOKLYN CITY HOSPITAL).—As a dressing (says the reporter in the *New York Medical Record*), the surgeons are very partial to styptic cotton, especially for chronic ulcers; first scarifying the surrounding tissues, applying a layer of the cotton, and strapping over this. The rapidity of cure is sometimes wonderful. Besides the power of healing, its antiseptic properties are good.

As a general local application for chancres and syphilitic eruptions, the following is used with marked success:

Ungt. zinci oxidi,
,, hydrarg. chlor. mitis, aa;

while for internal use the ward prescription is,

Hydrarg. biniodidi . . . gr. ij.
Potass. iodidi . . . ʒss.
Syr. sarsap. co.,
Aque, aa . . . ʒij.
M. ʒj. ter die.

Iodoform locally applied, after cauterising a chancre, seems to have a good effect. Oleate of mercury in the treatment of orchitis is used with benefit. Applied locally to the indurated testicle, absorption is often rapidly promoted, though its irritating effect to the skin is not pleasant.

As a treatment for specific bubo, ungt. hydrarg. locally applied, alternated with

Tincture of iodine . . . ʒiv.
Glycerine . . . ʒij.

M. Painted over the indurated glands.

In simple bubo, glycerine, externally, has been used with good results.

In phagedenic bubo, tartrate of iron and potash, internally and externally, is exclusively used.

Internal urethrotomy is employed in most cases of stricture with, as yet, no unfavourable symptom.

Hydrate of chloral has been used satisfactorily as an antiseptic lotion, gr. xx to the pint.

An interesting case of hydro-hæmatocele was admitted to the hospital. The patient was tapped for hydrocele in a New York dispensary. According to his statement he was cut twice, the first one being a dry tap, the second bringing blood. He was then sent home. Considerable hæmorrhage followed, and he was brought to the hospital showing signs of excessive bleeding. The scrotum was eighteen and a half inches in circumference, four times the size it was before the operation, and bleeding from two incisions. Hæmorrhage was controlled by pressure and cold applications. A few days after admission the scrotum was laid open, when it was found that the tunica vaginalis had not been pierced; the blood was external to the sac.

Delirium Tremens.—Treatment in these cases is very unsatisfactory; probably the most reasonable way is to give sixty grains of bromide of potassium, followed in an hour by twenty grains of chloral hydrate every fifteen minutes until three doses are

taken. If sleep be not produced, the medicine is to be discontinued and plenty of nourishment given, leaving the patient to wear it off.

Acute Dysentery.—Iced-water injections, with suppositories of morphia, and bismuth given internally, sometimes produce a rapid cure.

WALKER ON INOCULATION WITH BEE-POISON.—Mr. G. Walker, in the *British Bee Journal* (December 1, 1874), opens up the question as to whether immunity from the pain and other injurious effects of the sting of the bee can be obtained by inoculation. Visiting the Hanwell Apiary, he was struck with the mode in which the owner managed his bees, and asked him the length of time it required to render a person sting-proof. The reply was, that the son had only been a short time working with bees, and that he was quite free from any of the usual effects of bee-stings. Mr. Walker made the experiment upon himself, his *modus operandi* being to catch a bee, place it upon his wrist, and allow it to sting him, taking care that he received the largest amount of poison, by preventing it from going away at once; then he let the poison-bag work, which it does for some time after being separated from the bee. The first day he stung himself twice. The effect was rather severe cutaneous erysipelas, and disorder of the motor nerve, with the usual signs of inflammation. A few days having elapsed, and the symptoms having subsided, he caused himself to be stung again three times in quick succession. The attack of erysipelas was on this occasion not nearly so severe; still a stinging sensation ran up to the shoulder, and a lymphatic gland behind his ear increased considerably in size, the poison being taken up by the lymphatic system. A few days subsequently he was stung thrice, and the pain was considerably less though the swelling was still extensive. At the end of the next week he had had eighteen stings, and by the close of the third week thirty-two stings. After the twentieth sting there was very little swelling or pain, only a slight itching sensation with a small amount of inflammation in the immediate neighbourhood of the part stung, which did not spread farther.

MISCELLANY.

At the last meeting of the Paris Academy of Sciences, M. de Lesseps announced the capture of a female shark in the Suez Canal, containing in its abdomen twelve young sharks, all living, and varying in length from twenty to twelve centimètres. This fact, in the opinion of M. de Lesseps, tends to show that the shark is truly viviparous.

NEW FRENCH FACULTIES OF MEDICINE.—The French National Assembly has sanctioned the creation of two new faculties of medicine, one at Lyons, the other at Bordeaux. The same privilege was nearly accorded to Lille, but was finally refused in deference to the clerical party, who are there organising a faculty of medicine in harmony with the new law on the liberty of University teaching.

THE DOCTRINE OF HEREDITY.—Mr. Galton, in his recently published work, *English Men of Science, their Nature and Nurture*, gives the number of notable relatives of each grade which scientific men on the average possess. Thus, 100 scientific men have 28 notable fathers, 36 brothers, 20 grandfathers, and 40 uncles. The influence of the paternal and maternal lines is found to be approximately equal. Thus, 100 scientific men have 34 distinguished relatives on the paternal side, and 37 on the maternal side.

NEW YORK STATE INEBRIATE ASYLUM.—From September 1, 1873, to September 1, 1874, the number of patients admitted was 190, of which 23, or 13½ per cent. proved refractory and unsubmitive. The rest quietly submitted to the rules and discipline of the institution, and many have gone out, as is believed, fully restored. Measures are now being taken to inquire into the subsequent history of all those who have been inmates of the institution, to be embodied in the next annual report of the board of managers. Of these 190 inmates one has returned the third time, and sixteen are in their second term of treatment.

LYING-IN DISPENSARY AT KIEW.—The Faculty of Medicine of St. Vladimir, at Kiew, has just decided on creating a lying-in dispensary attached to the hospital service, for diseases of women and lyings-in. The object of this dispensary is to give to the whole of the poor population of Kiew the power, in case of necessity, in confinements, to obtain the advice of the principal physician or the principal obstetrician of the University. These functionaries will, on a requisition being made to them, send to the lying-in woman a medical student and a certificated midwife, who will take with them all necessary appliances. If the delivery prove too laborious or difficult, and an obstetrical operation be thought necessary, the principal obstetrician, on the requisition of the medical student in attendance, must perform it gratuitously; and should any illness follow the delivery, medicine will be given to the sick woman gratis.

HEREDITARY CRIME.—At a meeting of the State Charities Act Association of New York, Dr. Harris brought forward a remarkable history of a family which had pursued its unhappy career of crime and misery through six generations. It appears that some seventy years ago a young girl, named 'Margaret,' was left adrift in one of the villages in a county on the Upper Hudson—it does not appear whether through the crime or misfortune of others. There was no almshouse in the place, but she was a subject of outdoor relief, probably receiving occasionally food and clothing from the officials, but never educated, and never kindly sheltered in a home. She became the mother of a long race of criminals and paupers, and her progeny has cursed the county ever since. The county records show 200 of her descendants who have been criminals. In one single generation of her unhappy line there were twenty children; of these three died in infancy, and seventeen survived to maturity. Of the seventeen, nine served in the State prisons for high crimes an aggregate term of fifty years, while the others were frequent inmates of gaols and penitentiaries and almshouses. Of the 900 descendants through six generations from this unhappy girl, who was left on the village streets and abandoned in her childhood, a great number have been idiots, imbeciles, drunkards, lunatics, paupers, and prostitutes; but 200 of the more vigorous are on record as criminals.

DRINK.—Some extraordinary instances of the insatiate desire, or rather morbid impulse, to drink are mentioned in a paper on the *Insanity of Inebriety*, by Dr. George Burr, published in the *New York Psychological and Medico-Legal Journal* of December, 1874. Dr. Bush records a case in which he says, in reference to an habitual drunkard in Philadelphia, who, when strongly urged by one of his friends to leave off drinking, replied, 'Were a keg of rum in one corner of a room, and were a cannon constantly discharging balls between me and it, I could not refrain from passing before that cannon in order to get at the rum.' One of the cases described by McNeish, in his *Anatomy of Drunkenness*, as quoted by Dr. Ray, also illustrates this feature. A friend of the subject of it painted to him 'the distresses of his family, the loss of his business and character, and the ruin of his health,' to which he replied, 'My good friend, your remarks are just; they are indeed too true; but I can no longer resist temptation. If a bottle of brandy stood at one hand, and the pit of hell yawned at the other, and I were convinced that I would be pushed in as sure as I took one glass, I could not refrain.' The late Professor R. D. Mussey, of Cincinnati, relates another case: 'A few years ago a tippler was put into an almshouse in this State. Within a few days he had devised various expedients to procure rum, but failed. At length, however, he hit upon one which was successful. He went into the wood-yard of the establishment, placed one hand upon the block, and with an axe in the other, struck it off at a single blow. With the stump raised and streaming, he ran into the house and cried, "Get some rum! get some rum! my hand is off." In the confusion and bustle of the occasion a bowl of rum was brought, into which he plunged the bleeding member of his body; then raising the bowl to his mouth, drank freely, and exultingly exclaimed, "Now I am satisfied!"' Dr. J. E. Turner relates a case of a gentleman, who while under treatment for inebriety during four weeks secretly drank the alcohol from six jars containing morbid specimens. On asking him why he had committed this loathsome act he replied, 'Sir, it is as impossible for me to control this diseased appetite as it is for me to control the pulsations of my heart.'

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.: free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

WEDNESDAY, JANUARY 13, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CANTIERI ON THE ACTION OF CANTHARIDES AS A VESICANT AND RUBEFACIENT.

In his article on cantharides, in *Lo Sperimentale* (already quoted in the LONDON MEDICAL RECORD for December 23, p. 803), Dr. Cantieri makes the following remarks on the local action of cantharides.

Physicians apply blisters as a means of revulsion. What is this revulsion? Schiff, after having opened the thorax of a frog and laid the heart bare, struck the animal's abdomen with a small instrument, and saw the heart become small, pale, and bloodless, until at last its action altogether ceased. He then divided the aorta; only a very little blood escaped, which had been arrested in it. On opening the abdomen, he found its vessels extremely dilated (*Lezioni di Fisiologia Sperimentale*, compilata dal Dott. P. Marchi, Firenze, 1866). This is precisely what revulsion is.

Revulsives can only exert their action on removable elements, such as the blood and, perhaps, the contents of the lymphatics. Primary hyperæmiæ, or those which form the first element in inflammation, or the simple passive hyperæmiæ sometimes met with, are the only ones which can be removed by revulsives. And, in fact, we see certain states of hyperæmia produced by insolation, or by the abuse of alcohol, overcome by pediluvia of water, either simply warm or with mustard added to it, or by the action of stimulant frictions over the whole cutaneous surface of the body. I believe in the truth of revulsion; in the fact that a quantity of blood flowing to a part of the body may, by means of an irritant, be removed and conducted to another point.

But when inflammation is already developed, if the red and white corpuscles and the plasma have passed through the walls of the capillaries, and have already produced an increase in the size of the affected part, if, finally, what we call inflammatory exudation have taken place, then revulsion is altogether impossible. This stage of inflammation requires a special process for its completion. Either resolution, suppuration, induration, or gangrene takes place.

The agent of revulsion should be in proportion to the quantity of material that can be removed. Velpeau and Gendrin believed this to such an extent, that they applied blisters of enormous size; the former to a limb, to cut short a phlegmon, the latter to one-half of the chest, to subdue pleurisy or pneumonia. I do not very well know what effects they obtained; but, without referring to the experiments which I have performed, and judging solely from clinical experience, I much believe that, if the final result were successful, the direct effect on the part, and the indirect ones upon the internal organism, must have been very severe. And this is

because the revulsive action cannot be separated from the other action which depends on the absorption of the elements of cantharides—the alteration and destruction of the blood-corpuscles, along with the alteration of structure and disturbance of function of the nervous centres. I do not believe that the abuse of a remedy is justifiable, when there is reason to fear that it will injure to such an extent as to put the patient's life in danger in place of overcoming his disease. On the contrary, it is the duty of the physician to select other means, which are free from danger, although their action is less certain.

The method of Velpeau and Gendrin is simply substitutive medication—that is to say, the excitation of a visible external inflammation for the purpose of overcoming an internal one.

But such a mode of treatment is objectionable. There is not the least doubt that revulso-substitutive medication must always aggravate the condition of the patient, inasmuch as it develops a new focus of disease, it may be, indeed, external, of which it is not within the power of the physician to limit the extent or to moderate the effects which it must necessarily produce on the whole organism; and, in my opinion, such treatment must always be injurious, however pursued, and especially when blisters of cantharides are used for the purpose. For the good of humanity, the revulso-substitutive treatment ought to be eradicated from the list of remedies.

Besides substitution, revulsive medication comprises also rubefacient action; and this, being useful in certain conditions, may still be employed.

The action of a vesicant on the skin is eminently irritative. A few hours after its application it produces pain, redness, slight tumefaction of the part, then sero-albuminous exudation with raising of the epidermis, first into small vesicles, which become confluent and are united into a large blister. These effects are more or less active, more or less painful, according to the delicacy of the organism and to the morbid predisposition of the individual to whom the vesicant is applied. In slender, weak, and nervous females, we sometimes meet with lipothymia, or with convulsions, dependent, probably, on the pain produced by the vesicant. In lymphatic and obese individuals, on the other hand, vesicants, even when applied but for a short time, have been known to produce serious suppuration and sores difficult of healing; and in cases of typhoid fever, or of debility connected with subcutaneous serous exudation, extensive and deep sloughing, leading to pyæmia, ichorrhæmia, and death, has been produced.

The physician who judges it necessary to employ cantharides as a rubefacient, must attend to the following conditions.

1. To keep the vesicant applied for as short a time as possible; since its prolonged contact with the skin may lead to the absorption of a large quantity of the active principle of the cantharides, and to its consequent effects on the organism. In some cases, a large blister has risen some hours after the removal of the vesicant; the action is then destructive, and all the results above enumerated may arise.

2. Not to apply it to nervous, slender, and delicate individuals, in order to avoid the perverting effect of cantharidine and the debilitating effect of pain.

3. Not to apply it to patients suffering from fever arising from infection of any kind, lest, besides adding a toxic element to that which already exists, grave new changes be produced.

4. Not to apply it to persons suffering from chronic

heart-disease or other maladies attended with œdema or anæmia, and with great tendency to inflammation of the skin.

Putting aside these cases, I think that vesication with cantharides may be useful in medicine as a rubefacient in simple venous hyperæmia or stasis, such as arise from insolation, from the temporary abuse of alcoholic liquors, from heart-disorders, and other affections of this kind. But, although I would not absolutely oppose the use of cantharides, I would prefer sinapisms, or simple or sinapised pediluvia, frictions of the skin, and other kinds of irritants which are not attended with danger.

Finally, the following conclusions arise from the facts which I have studied and analysed.

1. Vesicants do not sustain or excite the action of the heart and vessels, but rather weaken and depress it.

2. The stimulant action on the heart seems to be better explained by the action of remedies administered internally, such as wine, ether, etc., than by that of the vesicants.

3. Vesication with cantharides is absolutely contraindicated in all cases of dropsy arising from active or passive hyperæmia of the kidneys; because the drug, exercising its irritant and perverting action on these secretory organs, augments the afflux of blood and thereby aggravates the morbid condition. Such treatment is to be absolutely prohibited in dropsies attending Bright's disease or cardiac disorders, especially if the presence of albumen in the urine intimate the existence of renal stasis.

4. Substitutive treatment cannot be carried out, since, besides the mischief arising from the extensive local action of a vesicant, there are the evils which may be produced from the absorption of the cantharides.

5. Vesication may be used as a rubefacient under the conditions already described.

6. In applying rubefacient treatment, it is best to have recourse to other irritants, such as sinapisms, pediluvia, etc.

7. In general, vesicants cannot be applied to the treatment of acute diseases without injury to the patient. They cannot be used in typhoid and in other infective fevers, in which an adynamic and ataxic state prevails, inasmuch as, in consequence of the absorption of the active principles of the cantharides, the blood-corpuscles are changed, the contractile power of the heart is diminished, and one infection is added to another; while on the other hand, changes are produced in the cerebro-spinal centre, which give rise to disorders of the vital functions dependent on them. Vesicants cannot be applied in any stage of inflammation, since they increase the hyperæmia, destroy the contractility of the vascular walls, and paralyse the vaso-motor nerves; or by altering the blood-crisis, they may produce changes in the products of inflammation. Finally, they favour cardiac collapse, instead of preventing it, as has been believed. A. HENRY, M.D.

ON ALIMENTATION IN DISEASE.

By DR. AUSTIN FLINT.*

Chomel, in his admirable treatise on General Pathology, defines the art or the practice of medicine to be the application of good sense to the treatment

of diseases. He adds that knowledge of diseases is indispensable, but good sense ranks first in importance. I give the literal translation of the French term, in preference to the phrase 'common sense,' which is generally used with us, inasmuch as good sense is rather uncommon than common. This definition by Chomel is not less just than striking. The ablest practitioners in the different departments of medicine have always been those who, in addition to an abundance of knowledge, possessed in an uncommon degree good sense. This is as true now as hitherto. How often do practitioners, by no means deficient in medical knowledge, fail in practice because they lack good sense! and, on the other hand, good sense often compensates to a considerable extent for deficiency in medical knowledge. The great improvement which has taken place within the last quarter of a century in the practice of medicine, as regards the employment of remedies, and, still more, the hygienic management of diseases, is due not less to the agency of good sense than to pathological researches. Good sense restrains the formation or adoption of baseless speculations and immature doctrines; it prevents one-sided and extreme views; it opposes alike presumptuous innovations and bigoted conservatism; it keeps within proper bound reliance upon others and self-reliance, discouraging equally blind partisanship and dogmatic egotism; and, finally, good sense is the true genius of medical experience. With these preliminary remarks, I proceed to submit to the good sense of those whom I address some considerations relating to an important subject in practical medicine, namely, Alimentation in Disease.

As conducive to a proper appreciation of the importance of alimentation in disease, the natural history of starvation is to be considered. The immediate effects of starvation are, of course, most rapidly produced and most strikingly manifested when all aliment is withheld. The blood is notably diminished and impoverished, emaciation is rapidly progressive, and death, according to the painful experiments of Chossat on inferior animals, takes place when the body has lost one-fifth or one-fourth of its weight in health. The more obvious phenomena attendant on these immediate effects are as follows. Febrile movement frequently occurs, although the temperature of the body is greatly reduced before death; muscular debility is speedily a marked symptom, and is soon followed by great prostration; the circulation is more and more enfeebled; there is inability to sleep; the moral sentiments are perverted, and, after a time, there is delirium, which is sometimes active and sometimes passive; diarrhœa often occurs, and the breath becomes intolerably fetid. The average duration of life, the complete deprivation of aliment being understood to include water, varies from five to eight days. The mode of dying is typical of slow asthenia, or exhaustion. The phenomena are essentially the same, but the duration of life is considerably longer, if water be not withheld.

The phenomena of starvation are not confined to cases in which there is complete deprivation of aliment. This is a fact highly important in its bearing upon alimentation in disease. Starvation is produced whenever the aliment is insufficient, either as regards quantity or quality, for repairing the losses which the blood sustains in supplying to the solids materials for nutrition. The phenomena of starvation are essentially the same as when all nourish-

* Reprint of a paper read before the Medical Society of the County of New York.

ment is withheld ; the only difference being that they are developed more or less slowly, they are consequently less striking, and their connection with deficient alimentation is liable to be overlooked. Another fact relating to starvation also has an important bearing on alimentation in disease—certain portions of the body may suffer from the want of materials in the blood proper for their nutrition, while other portions of the body are sufficiently nourished. To quote the language of the author of an able essay on 'Army Alimentation,' 'Starvation is a comparative phrase. We can starve muscle by withholding nitrogen. We can starve the fats of the body, and destroy the animal heat, by withholding carbon. So, too, we can starve the brain by withholding phosphorus ; and starve the blood by failing to supply it with those salts of lime, potash, soda, iron and magnesia, which are essential to its healthy condition.*'

Recognising the fact that the term starvation comprehends all degrees of innutrition between the extreme degree produced by the deprivation of all aliment, and the opposite extreme caused by a slight diminution of the alimentary supplies requisite for the wants of the body, and, also, that certain parts may be starved while other parts are amply nourished, I proceed to state another fact, the practical bearing of which on alimentation in disease will be at once apparent. Starvation may be produced in persons affected with different diseases, as well as in healthy persons. There is nothing in disease to prevent starvation or its immediate effects. Starvation is sure to occur in cases of disease, in a degree proportionate to the lack of material for nutrition in the blood ; in other words, in proportion as the requisite amount of aliment is either not ingested or not assimilated. The immediate effects and the attendant phenomena are the same when starvation occurs in connection with disease, as when it is produced in persons previously in health. Impoverishment of the blood, emaciation, febrile movement, followed by a reduction of the animal temperature, feebleness of the circulation, vigilance, perversion of the moral sentiments, delirium, diarrhoea, and fetor of the breath may be attributable, in cases of disease, to starvation. In connection with all diseases, more or less of the morbid phenomena present arise from starvation, and these phenomena are prominent and grave in proportion to the degree in which either alimentation or assimilation is defective. Chossat has enunciated truths in language which enforces their importance, when he says, 'Starvation is a cause of death, marching silently in front with every disease in which alimentation falls below the natural standard. It reaches its natural termination sometimes sooner and sometimes later than the disease which it covertly accompanies ; and it may supersede the disease of which, at first, it was merely an incidental element.' Starvation is often the immediate cause of death, when diseases destroy life by slow asthenia or exhaustion. If a fatal termination be not due to a direct interference with the action of the heart, or with respiration, it is correct to say, that patients die because they are starved to death. Certain it is that diseases which do not compromise directly the function of either the heart or

lungs, cannot kill so long as the nutrition of the body is maintained at a point compatible with life. Starvation, associated with disease, may be inevitable ; that is, the disease may involve an insuperable obstacle to either the ingestion of aliment, or its assimilation. Then it is that, in the language of Chossat, inanition may reach its termination sooner than the disease. On the other hand—and here is a fact full of practical import—starvation may not be a necessary effect of the existing disease, but may be due to insufficient alimentation. In such cases, inanition may prove a cause of death when the disease need not have destroyed life ; the patient, indeed, may die of starvation notwithstanding the progress of the disease *per se* be favourable. Then, in the language of Chossat, inanition 'reaches its natural termination later than the disease which it covertly accompanies, and it may supersede the disease of which, at first, it was merely an incidental element.'

On these facts pertaining to starvation, rest the practical considerations relative to alimentation in disease, which I shall now proceed to submit.

A logical inference from these facts is, that to prevent starvation is of fundamental importance in the practice of medicine. The importance of this object in the treatment of individual cases of disease, is to be estimated by the amount of impending danger from starvation as an incidental element. All who hear me are doubtless familiar with the teachings of Graves, with respect to alimentation in the continued fevers. Graves states that he was first led to appreciate the importance of giving nutritious food in cases of fever, by the remark of a shrewd country practitioner, who said that, in his practice, patients generally recovered if he could prevent them from being starved to death. Graves inaugurated a great reform in the treatment of fevers as regards alimentation ; and as proof of the strong conviction in the mind of this distinguished clinical teacher of the improvement in practice which dates from his publications, he is said by his co-worker Stokes to have declared that he could desire no better epitaph than, 'He fed fevers !' Few, if any, practitioners at the present day are disposed to undervalue the importance of alimentation in the essential fevers ; but it is not less important to prevent, if possible, death from starvation in all other diseases. If to die by slow asthenia be often virtually to starve to death, then, no matter what the disease may be, it is an object of fundamental importance to promote, as far as practicable, the assimilation of food. Looking at the object of treatment in another point of view, it is customary to say that the powers of life are to be supported in proportion to the danger of death by asthenia, whatever be the nature or seat of the disease. Now, of supporting measures, alimentation holds the front rank, not depreciating the importance of stimulants, especially alcoholics, which it is foreign to my present purpose to discuss.

Admitting the fundamental importance of alimentation in the treatment of diseases, the inquiry arises, what are its limitations ? In answer to this inquiry, it is to be stated that, if we except the early stage of some acute diseases in which it may be an object to withhold aliment with an indirect reference to depletion, there is never any risk of hypernutrition. With the exception just stated, I submit the proposition that it is always desirable, in cases of disease, to supply aliment to the fullest extent of

* Dr. S. B. Hunt, vide *Sanitary Memoirs of the War of the Rebellion*, vol. i. of the series published by the U. S. Sanitary Commission.

the capacity of the organism for appropriation. In acute diseases, the failure of the vital powers is forestalled in proportion as nutritive supplies are assimilated. This is simply saying that the assimilation of nourishment is indispensable for the preservation of the powers of life. And when, in the progress of an acute disease, more or less failure of the vital powers ensues, the more nutrition can be maintained, the more efficient the support. The proposition just submitted embraces not only the acute but the chronic diseases. No matter what may be the seat or the nature of the chronic affection, a diet fully up to the capacity of the organism for nutrition promotes recovery, if recovery be possible, and, if recovery be not possible, by increasing the ability of the system to endure the affection, contributes to prolong life. The limitations to alimentation, therefore, relate wholly to the physiological processes which are preliminary to nutrition, namely, digestion and the other processes by which aliment is converted into blood. If more food be ingested than the digestive organs can prepare for assimilation, or if the articles of diet be not suited to the digestive powers, the nutrition will not be in proportion to the alimentation, and disorder of the digestive organs may be produced. This is, of course, if possible, to be avoided; yet, the harm resulting from over-alimentation is generally exaggerated. Undigested aliment often passes through the alimentary canal without causing any appreciable disturbance. The disorder which may be produced is due chiefly to chemical changes in the ingesta, and is manifested by flatulence, pain, and looseness of the bowels. Conservatism is seen here as in other morbid effects. As the result, the offending matter is expelled, and the harm is, in general, not more than that caused by a cathartic or laxative. It is quite superfluous to say that to avoid over-alimentation may be highly desirable, but it is sometimes safer to incur risk in that direction, than to limit alimentation below the ability of the digestive powers and the capacity of the organism for nutrition. What rules are to govern the practitioner in so regulating alimentation in disease as to avoid the evils, on the one hand, of starvation, and, on the other hand, of disorder of the digestive organs? To treat of the numerous topics which this question opens up, is impossible within the limits of a brief discourse. In the few moments remaining of the time to which I have restricted myself, I can only submit, without discussion, some of the considerations suggested by the question. An unwillingness to presume upon the patience of my auditory must be my apology for offering statements open to criticism on the score of their having the character of aphoristic propositions.

As the first in rank of supporting measures in the management of the essential fevers and all acute diseases which endanger life by asthenia, it is often necessary to regulate alimentation without regard to indications afforded by appetite or taste. In many cases of disease, owing to bluntness or perversion of the mental perception, the wants of the system as regards nutrition are not indicated by a desire for food, or by choice in its selection and preparation. Patients not infrequently die of starvation without having experienced any sense of hunger. Under such circumstances, the rule is to supply, not only as much aliment as the digestive organs can prepare for assimilation, but food containing, in proper amounts, all the alimentary principles required to repair the waste of the different parts of the organ-

ism. Limiting alimentation to an article of food inadequate as regards the different alimentary principles which it contains, will not prevent starvation, no matter how abundantly the article is ingested. For example, patients may be starved to death on the juice or a decoction of beef given without stint and digested. The risk of starvation is much greater if the diet be restricted to substances less nutritious, such as gelatin, albumen, starch, or gum. The valuable experiments of Hammond and others have established the fact that the last three of these alimentary principles, namely, albumen, starch, and gum, singly, are wholly inadequate to nutrition; and the inadequateness of gelatin was long ago settled by the famous Gelatin Commission in Paris. Under the circumstances stated, the diet should not only embrace the requisite variety of alimentary principles, but food must be given in a concentrated and liquid form. Milk, *par excellence*, has these recommendations, and is, therefore, of all articles of diet, in fevers and other acute diseases, to be preferred. The alimentation is rendered more effective by the addition to milk of a farinaceous substance, and by alternation with animal broths, or the essence of meat. Eggs, also, form an excellent article of supporting diet, owing to the fact that they contain the requisite variety of alimentary principles combined by the hand of nature. Whenever alimentation is a measure of support, that is, whenever there is danger, either immediate or remote, from starvation, an important rule is to allow always, after food has been given, a sufficient period to judge whether or not it produces disorder of the digestive organs. The intervals should be from three to four hours. If food be given every hour or half hour, as is often done, the organs of digestion have no period of rest, and it is impossible to form any judgment concerning the digestive powers. Moreover, after intervals sufficient to allow rest, food is more likely to be digested. A grave objection to giving food after very short intervals, is that it involves interference with sleep and occasions both physical and mental annoyance. By allowing sufficient intervals, the quantity of food may be graduated to the digestive powers, and thus disorder from over-alimentation avoided.

An important rule of alimentation in fevers and acute diseases, relates to variation in the articles of diet and in the preparation of food. Any article, prepared in a certain mode, and given, without change, day after day, becomes, after a short time, offensive and disgusting. The patient takes it, not merely with indifference or against inclination, but with strong aversion; and this is an evil, not alone on the score of difficulty and annoyance in giving nourishment, but because, under these circumstances, the digestive organs, as well as the palate, rebel against it. Variations may be made by giving, on successive days, the decoction or juice of different kinds of meat; by adding to milk different farinaceous substances, and by different modes of preparation. This rule, like most other dietetic rules, will not be carried out unless the practitioner be precise and enter into minute details in his directions concerning alimentation. Persons upon whom devolves the nursing of the sick, often attach little importance to the diet; they are apt to imagine that everything depends on remedies. The physician not infrequently meets with opposition to his measures of alimentation, arising from a prejudice against feeding patients. It has been a popular notion that

starvation, so far from being the mode in which diseases are apt to kill, is a means of cure. Like other popular notions concerning diseases, this doubtless was derived from the medical profession. It is but a short time since the *cura famis* was relied upon in the treatment of most of the acute and many of the chronic diseases. Notions thus derived are often retained in the popular mind long after they have been abandoned by the profession. The introduction by enema of aliment, when it is not retained by the stomach, is often highly important.

Whenever patients desire certain articles of food, as a rule, these are to be allowed. Such a desire, if distinct, represents generally a want of nutrition, more reliable than the judgment of the physician as to the articles best suited to the case. Every one has heard of instances in which patients have craved articles of food considered as extremely inappropriate, but the cravings being indulged, perhaps without the sanction of the physician, marked improvement immediately followed. Remarkable instances of this kind are undoubtedly authentic, and they are striking illustrations of the soundness of the rule just stated. This rule is in conflict with a popular notion, for the origin of which the profession is doubtless responsible; namely, that in cases of disease the instinctive desires are morbid, and are to be opposed rather than indulged.

Alimentation, as a measure of support, is more important in cases of disease affecting the young and the aged, than during the intervening periods of life. This is consistent with the fact that starvation kills children and old persons more quickly than those who have attained to full development and who are not in advanced years. Of the 150 persons who, after the wreck of the frigate *Medusa*, were exposed on a raft for thirteen days, with hardly any food, children, young persons, and the aged, were the first to die from starvation.*

During convalescence from fevers and other acute diseases, the ordinary articles of solid food should be allowed, as soon as they are desired. Convalescence is protracted by the continuance of a liquid diet, and by an insufficient alimentation. The kind of food may, in general, be safely left to the choice of the patient, and the quantity is to be graduated by the activity of the digestive powers and of nutrition. The risk of over-alimentation during this period is often exaggerated; and, with reference to alimentation, as well as to other measures, it is to be considered that after many diseases, for example, the continued fevers and pneumonia, the liability to relapse is exceeding small.

In the management of chronic diseases, measures aside from alimentation, whether medicinal or hygienic, are serviceable in proportion as they contribute to digestion and nutrition. Whatever be the nature of the chronic disease, or wherever it be seated, it is always an object of fundamental importance to keep nutrition as near as possible to the standard of health. The rules of alimentation, therefore, in cases of chronic disease, relate to the most efficient means of effecting this object.

Medicines not infrequently impair the appetite and interfere with digestion. If not required for a special curative effect, they are then likely to do harm by compromising, more or less, alimentation and nutrition. Hence, in fulfilling therapeutical indications, an important rule is to select remedies or phar-

maceutical preparations which are not offensive either to the palate or to the stomach. In prescribing remedies, allowance is always to be made for the wide difference among different persons as regards the gustatory and gastric sensitiveness to medicines. The over-drugging which formerly prevailed was in no small degree objectionable on account of its effects on appetite and digestion, aside from other effects. In this aspect, the use of drugs with far more discrimination and reserve now than formerly, is a great improvement; so, also, is the use of concentrated remedies, the preparation of medicines in agreeable forms, and the hypodermic administration of certain articles.

Efficient alimentation in cases of chronic disease is often impeded by prevalent popular errors. The notion that starvation is a means of cure, to which allusion has already been made, operates largely against an analeptic diet. Another popular notion is that the restriction of diet to a very few articles, and to the same articles continuously, is desirable; whereas, nothing is more certain than that a varied diet is most conducive to digestion and nutrition. As results of these errors, it is not uncommon for persons with some chronic ailment, and even healthy persons, not only to become feeble and anæmic, but to suffer, more or less, from the blood-changes which are embraced under the name scorbutus. Chronic affections are in this way protracted, the ability of the system to bear them is impaired, and serious ailments are thereby superadded. Other absurd popular errors relate to supposed individual peculiarities. Many persons seem to be pleased with the idea that articles of diet which are wholesome for mankind in general are pernicious to them. Practitioners daily meet with cases illustrating this strange manifestation of egotism. How often do we hear the trite saying that 'what is one man's meat is another man's poison,' a maxim which has very little foundation in truth. I suppose every one present has often met with objections to milk and eggs, which, as representing all the constituents of the organism, may be called the typical foods, on the ground that they are apt to promote biliousness! It will be a great gain, as regards alimentation in chronic diseases, when these and other errors of the same sort are completely eradicated from the popular mind.

It is highly important to consider the influence of the mind on appetite and digestion, and thereby on assimilation and nutrition. Not a small number of the disorders referable to impoverishment of the blood and innutrition are traceable to mental depression, which sustains to various disorders the relation of both cause and effect. Hence, in great part, the advantage, in many cases, of change of scene and new associations, the benefit being derived through the mind. Hence, the greater success of those physicians who take proper cognisance of the mental condition, in these cases, as compared with those whose professional offices are limited chiefly to prescribing drugs. Hence, too, the marvellous effect often of judicious encouragement, on the part of the physician, for mental depression in many cases relates to apprehensions which are either groundless or greatly exaggerated. The influence of the mind upon digestion is strikingly shown when, unhappily, patients have fallen into the habit of concentrating the attention upon the sensations which follow the ingestion of different articles of diet. If food be taken with distrust and anxiety lest

* *Physiology of Man.* By A. Flint, jr., vol. ii. p. 16.

it prove hurtful, the chances are it will give more or less trouble; and if taken with a pre-conviction that it will do harm, this result will be pretty sure to follow.

Having reached the end of the time which I resolved, on commencing to write, that I would not exceed, I must leave untouched many of the topics which suggest themselves in contemplating the subject of this discourse. The few and somewhat desultory considerations which have been submitted, relate entirely to alimentation when disease exists. A kindred subject is alimentation in health, considered with reference to the prevention of disease, to the development and growth of the organism, and to mental and physical vigour. The latter is a subject large in extent and of vast importance. With regard to this subject, as well as to alimentation in disease, notwithstanding the knowledge acquired and the improvements made within late years, there is yet abundant scope for further information and progressive practical progress.

My remarks have had reference, almost exclusively to one aspect of the subject, namely, the danger from defective alimentation, or starvation. The evil consequences of excessive and improper alimentation, both in health and disease, enter into another aspect of the subject. Considered in the latter aspect, the subject is one of magnitude and importance. Unquestionably, the evil consequences of excessive and improper alimentation are not always sufficiently appreciated by all members of the medical profession; and, with the well-known tendency in the doctrines and practice of medicine to opposite extremes, a full apprehension of the danger of defective alimentation is doubtless liable to be followed by error in an opposite direction. Under the necessity, however, of limiting the scope of my remarks, of the two aspects of the subject I have confined myself, for the most part, to the one which, at the present time, as regards the occasion for suggestive considerations, seems to me relatively the more important.

ANATOMY AND PHYSIOLOGY.

LADENDORF ON THE ACTION OF NITRITE OF AMYL ON THE BLOOD-CORPUSCLES, AND ON THE TEMPERATURE OF THE BODY DURING INHALATION OF THIS SUBSTANCE.—No. 43 of the *Berliner Klinische Wochenschrift* commences with an article by Dr. Aug. Ladendorf, writing from the Sachsenberg Lunatic Asylum, where his observations, embracing more than forty cases, were made, partly upon sane persons, and partly on those recovering from different psychoses. The time selected was generally from 3 to 5 P.M., or after 8 P.M., thus avoiding times when a normal rise of temperature might be expected. The thermometer was placed in the mouth, between the cheek and the superior maxilla—a space almost shut off by the tongue from the nasal respiratory tract. The readings were made by the help of a lens magnifying six times, so that by using a thermometer divided into tenths it was possible to recognise, without much chance of error, $\frac{1}{100}$ th of a degree Centigrade, equal to $\frac{1}{55}$ th of a degree Fahrenheit nearly. The general result is, that the temperature always rises after the inhalation. Many circumstances affect the amount of this rise—such as the quantity of vapour inhaled,

the surrounding atmosphere, the contraction of blood-vessels, individual peculiarities, etc.; so that two persons with the same initial temperature may show differences of 0.53° Cent., equal to 0.95° Fahr. It is, however, interesting that this rise can generally be demonstrated for from one to two hours, for this explains the beneficial and continued effects of the remedy in disease. A table of thirty-six cases is given, with the temperatures observed, the differences, their maxima, and remarks. The smallest maximal elevation of temperature was 0.1° Cent., equal to 0.2° Fahr. nearly (in three cases); the highest maximal rise was 1.88° Cent., equal to 3.38° Fahr. (one case); the mean rise was 0.39° Cent., equal to 0.7° Fahr. (thirty-six cases); or, in other words, the temperature rises rather more than half a degree Fahrenheit after the inhalation of nitrite of amyl. This elevation is very evident in the course of the second minute of inhalation. The purer the preparation inhaled, the more evident the effect. The effect on the pupils was not very uniform. In all the cases when simultaneous observations were made, the axillary temperature rose correspondingly. Horatio Wood (*American Journal of the Medical Sciences*, cxxiii.) and Pick (*Ueber das Amylnitrit und seine therapeutische Anwendung*, Versuch 13) observed a fall of temperature in animals; but perhaps this resulted from the mode of experimenting. Hösternann's account of the pulse (*Wiener Med. Wochenschrift*, 1872, nos. 46, 47, 48) is confirmed by these experiments. These effects, probably, have a common cause—not mere dilatation of the vessels. Ladendorf and Dr. O. J. B. Wolff investigated the action of nitrite of amyl on blood by microscopic examination. A drop of freshly drawn blood was placed on a slide under the objective, and a little spill of wood moistened with amyl nitrite approximated. When the spill was $1\frac{1}{2}$ to 2 millimètres (equal to $\frac{1}{16}$ to $\frac{1}{13}$ of an inch nearly) distant from the blood-drop, there immediately occurred, independently of the movements in the blood-fluid, a violent agitation of the blood-corpuscles in the neighbourhood of the spill: moving rapidly away from it, and returning, rather less quickly, to their old place, in a curved line, and then madly hastening (*sic*) to begin the same game again. Simultaneous experiments with indifferent bodies gave only the ordinary physical movements. The direct contact of the amyl nitrite is said to have produced solution of corpuscles, with formation of lake-like pigment (colour of winter-cherry). The vapour first made the corpuscles pale, then dissolved them. Ladendorf did not employ a moist chamber; but he ascribes the whole of the effects of amyl nitrite to this action on the blood-corpuscles—causing a backward pressure on the pulmonary arterial system first, and then on the systemic—finally inducing venous congestion as a natural consequence. He recommends the inhalation of amyl nitrite for anæmic headaches and epileptiform attacks occurring with subnormal temperatures, especially those of the head; in one case the fits were lessened by two-thirds. He confirms Pick's observation (also made by others) as to objects appearing yellow after the inhalation; and advises the lips, nostrils, etc. to be guarded from direct contact, as vesication is apt to arise if they are not so protected.—[The Reporter thinks this experiment on the blood-corpuscles extremely interesting, but by no means conclusive. Many other volatile bodies produce similar effects under the like

circumstances; and to ascribe all the phenomena seen after inhalation of amyl nitrite to a similar action within the vessels, on the faith of one experiment crudely made, is to generalise too hastily. —*Rep.*]

W. BATHURST WOODMAN, M.D.

PALMER ON THE EFFECT OF ALCOHOL IN HEALTH.—Professor A. B. Palmer, of the University of Michigan, has an article in *The Peninsular Journal of Medicine* on the action of alcohol. He starts with the assertion of the late Dr. Anstie, that about ten drachms of absolute alcohol may be taken in a diluted form by a healthy adult in the course of twenty-four hours, without producing any noticeable disturbance of the system or any of it being capable of detection in the excretions. Dr. Anstie also thought that, if it is not oxidised in the system, of which there is no actual proof, it must undergo some unknown transformations by which a certain amount of force is set free. Professor Palmer urges as objections to these statements that Du Roy and Perrin, of Paris, have averred that all the alcohol taken into the system is eliminated unchanged; and he thinks that our methods for detecting so small a quantity are so imperfect as to render it impossible to come to a reliable conclusion upon the point. And even admitting that such a transformation occurs, it does not follow that the latent force of the alcohol is translated into vital force. Also, the increased force, did it exist, would be more than counterbalanced by the narcotic action of the drug, which must have the same tendency in small as in large doses. He thinks that such theoretical arguments are not of much use either on the one side or on the other, and that, in determining the question, we must have recourse to the observation of its effects upon the capacity for mental and bodily work. For proof of his position, he relies mainly upon the report of Professor Parkes, which appeared in the *Lancet* for August, 1874, respecting the issue of spirit-rations in the late Ashantee war. The facts, separated from opinions, are as follow. Of twenty-four total abstainers in the 42nd regiment, only four were ill during the whole campaign, and none of these more than once, while those who partook of the rations showed a much higher ratio of sick; the exact proportion being one to six of the former, and four to six of the latter. The difference was no doubt largely due to the previously more correct habits of the abstainers. In the rifle brigade the ratio of admissions to the sick-list was 770 to 1,000 strength, 574 being from fevers and 196 from other causes. Of the abstainers, the ratio was 400 to 1,000, and all from fevers. All the witnesses testify against the utility of rum when given in the morning, but several spoke of its reviving effects when given at the end of the day. This illustrates the narcotic or anodyne power of the alcohol, but gives no evidence that it imparts even temporary strength. According to Dr. Parkes, the experience of the Red River expedition 'has produced a general belief that spirits were in all cases hurtful, or, at any rate, unnecessary in military service.' In a hot, moist, enervating climate there is a desire for something to relieve the uncomfortable sensations produced by severe exertion; but Dr. Parkes regards alcohol as the 'most faithless of helps,' and as a stimulant and not a renovator of exhausted tissues. Meat-extracts, on the other hand, act in great part by supplying to the muscles the material they want. What grounds, then, have we for calling alcohol a stimulant in

the ordinary sense of that word as that which increases vital action? And, if it does not supply materials to exhausted tissues, what grounds are there for calling it a food? In summing up, Professor Palmer warns medical men against recommending its habitual use as an article of diet.

JAMES ROSS, M.D.

POUCHET ON CHANGES OF COLOURATION IN VARIOUS ANIMALS, UNDER INFLUENCE OF THE NERVES.—The French Academy has just announced its distribution of prizes for two years. The various reports on these will be found in *Comptes Rendus* (December 28.) We note, *inter alia*, that the Montyon prize, in experimental physiology, has been awarded to M. Pouchet for a memoir on the subject stated above. The following is an abstract of the Commission's report, in connection with this prize.

The memoir is in two parts, one purely anatomical, the other physiological. The former contains new facts, but it is the latter that has chiefly engaged the attention of the Commission.

From this point of view the work is almost without precedent. It was widely believed, indeed, that the skin of certain fishes took the colour of the bottom on which they lived; but exaggeration often deprived statements to this effect of their value.

In 1830 certain experiments on the subject, by Stark, were described in the *Edinburgh New Philosophical Journal*. Putting fishes in vessels enclosed in dark or in bright cloth, he perceived that the colour of the animals changed in the same direction, becoming darker or brighter; but he abstained from giving an opinion as to the internal conditions of production of this phenomenon.

It has been shown by physiologists, further, that the colour of the frog's skin may be modified from various causes, section or stimulation of the nerves, various conditions of habitat in water or air, etc.; but it was pretty generally agreed that these changes might be explained by disturbances in the circulation, due to the various modes of treatment, and bringing about in their turn a change in the state of dilatation or of contraction of the pigmentary cells. The special feature of M. Pouchet's experiments is that they show the pigmentary cells or chromoblasts to be in direct and immediate dependence on the nervous system; so that they must be added to the list of anatomical elements, in which nervous excitation is transformed into mechanical work. The nerves determine contractility of the chromoblasts, as well as that of striated fibres of voluntary muscles and fibre-cells of the muscles of vegetative life.

The author first verifies the fact that certain kinds of fish, such as young turbot, placed successively in water on bright and dark bottoms, show very rapid changes of colour, or tone, produced by dilatation or contraction of the chromoblasts charged with dark pigment, more especially those having the rôle of changing to brown, or abating more or less the proper colouration of neighbouring parts. As there are also, however, contractile cells charged with coloured pigments varying from red to yellow, it may happen that, by the state of relative contraction of these different elements, the shade of the animal may be modified in a certain measure.

If in most of the species presenting these changes it is difficult to make out the influences which cause them, there are other species in which the determining conditions may be ascertained with ease. Let a turbot, measuring only twelve to fifteen cen-

timètres, rest for some minutes over a light bottom, such as one of sand, and it becomes pale in unison with the sand; let it rest, on the other hand, over a rocky bottom, and it grows brown like that. One has only to contrast two animals placed under such conditions, to ascertain that the brightness of their colouration corresponds exactly to that presented by the colour of the two bottoms. We may thus produce indefinitely, in the same animal, a considerable change of colour, which does not require more than twenty to forty minutes for its production, and is sometimes much more rapid.

M. Pouchet calls this power which the animal has, its chromatic function. It is subject, within variable limits (according to species), to the influence of the nervous system. The colour of several species of fish was observed to change when they were irritated, or on simple sight of an external object. And since the changes depend on the greater or less absorption of light by the bottom, they must be regarded as true reflex acts, having their centre in the brain, and their starting-point in retinal impressions. The fundamental experiment in M. Pouchet's work is that in which he suppresses the chromatic function by removing the ocular globe, or simply cutting the optic nerve. The blinded animal loses its power of changing colour according to the bottom.

Having thus first established that the dilatation or contraction of the chromoblasts does not depend on local conditions produced in these elements at that point in the organism which they may occupy (as was previously thought), but is determined at a distance, by antecedent change of the elements of the central nervous system, it remained to find out by what route this transmission takes place, from the brain to the pigmentary cells of the periphery.

The author made various sections of nerves, and he has demonstrated that the spinal cord is not the nervous conductor, nor yet the lateral nerve, to which it seemed natural to attribute a rôle in this function. The trigeminus, on the other hand, has a direct action. Turbots taken from off a brown bottom, and, after section of the trigeminus, placed in a basin with sandy bottom, grow pale over their whole surface, except the face, which remains shaded, as if covered with a mask. Section of the spinal nerves gives results no less distinct. It confirms what has been said about the negative rôle of the cord. For the section of spinal nerves to influence the chromatic function, it is necessary that it be made below the point where they receive the thread of the great sympathetic. The result is a transverse dark band marking the region under the influence of mixed nerves receiving the cut sympathetic fibres.

It is, then, the great sympathetic which governs the chromatic function. It forms the route of transmission for the influence going from the brain to the cutaneous chromoblasts. The disposition of this nerve in fishes, lying as it does in the same osseous canal with the principal artery and the principal vein of the body, does not allow of the section being made with advantage directly, as grave disorders ensue, which spoil the experiment. But the result of section of the mixed nerves, as above, sufficiently attests the influence in question.

The author has not confined himself to fishes; he has shown that the chromatic function also exists in some articulata; more particularly in *Palaemon serratus*. It may be demonstrated in the way that has

been indicated for fish. Removal of the eyes, also, suppresses the function; at least till these organs are regenerated. But M. Pouchet did not succeed in finding what route the nervous influence took in crustacea, from the cerebral ganglions.

M. Pouchet's observations establish, it will be seen, a series of new facts, which have, moreover, a remarkable character of generality. They open up an unexplored region, by revealing a series of reflex actions, of which the retina is the starting-point, and which irradiate over the whole system.

These researches were prosecuted at Concarneau, in the laboratory founded by M. Coste, which has already yielded various important scientific results.

MEDICINE.

GLAX ON A CASE OF ENTERO-STENOSIS.—In Nos. 45 and 46 of the *Allgemeine Wiener Medizinische Zeitung* (Nov. 3 and 10, 1874) is the following case, reported by Dr. Julius Glax, from Professor Körner's wards. J. Prates, aged twenty-six, an attendant in the eye wards, stated that he had several times suffered from peritonitis, always after errors in diet, or exposure to cold. For about a year he had felt quite well, except that his bowels were often constipated. Fourteen days before admission, some imprudence in diet brought on colicky pains in his abdomen, his bowels becoming constipated at the same time. A calomel and jalap purge, which usually relieved him, did not operate; the pains increased, he lost his appetite, and was forced to seek

admission into the wards. On his admission on July 1, his condition was as follows. He was free from fever, the tongue was slightly coated, respirations twenty-four per minute. The abdomen was flat, resistant, not tender on pressure below, but above the navel on both sides of the linea alba, and especially on the right, there was a tumour discoverable, which resisted attempts to move it, and appeared very tender. The percussion-note from the xiphoid cartilage to a finger's breadth below the navel, and for about two inches in width to the right of the linea alba, was perfectly dull and hollow, and about a half-inch to the left of the middle line very tympanic and hollow. The liver dulness was continuous with the above-named in the parasternal line, otherwise normal. Except a slightly hollow sound at the right apex, the thoracic organs appeared normal. Pulse, 88, small and hard. It appeared probable that this was a collection of fecal matters in a rather uncommon situation, viz., the transverse colon. The extreme tenderness did not allow attempts to displace these scybala by pressure, especially as it was probable that there was enteritis. To promote action of the bowels the abdomen was painted with glycerine of iodine (iodi \mathfrak{O} j, potassii iodidi grs. x, glycerini \mathfrak{z} ss) and covered with thin gutta percha, so as to produce considerable cutaneous irritation. Internally, an ounce of castor-oil with fifteen drops of chloroform was given (a very useful combination, and well-borne by the stomach in cases where the castor-oil alone would be rejected, which seldom happens when thus combined with chloroform). In this case five stools quickly followed, containing a good many scybala. Next day the patient felt much better; pulse, 96; respiration, 24; temperature, 97.8°. The tumour had almost vanished. Percussion was generally clear, full and tympanic, except that to the right of the linea alba, about two finger-breadths below the edge of the liver, there was a spot of increased resistance and tenderness, and duller percussion-note. Five leeches over this gave some relief. On July 4 there was again considerable dulness below the liver, and less tenderness. A clyster produced a copious feculent stool. On the 5th there was more dulness. Iodine-paint was again applied, and the castor-oil with chloroform was ordered again; three stools with hard lumps resulted. On July 6 the patient felt pretty well; pulse 80, respiration 24, temperature 98.3° Fahr. On the 7th, although percussion was normal, the patient felt violent pains on the right side, below the liver. The temperature rose to 100.4°, the pulse again to 96. Five leeches again relieved. About 2 A.M. on July 8, the patient was found in great pain, and crying out loudly; the abdomen was much distended; the percussion-note was everywhere clear and full, not tympanic. He had hiccup, and vomited bile-tinged fluid. Pulse 96, small and weak; temperature 99.8°. Invagination was suspected, and a general warm bath ordered, with repetition of castor-oil and chloroform. This was immediately vomited, and the pains remained unabated; next day there was no improvement. There was vomiting of matters with fecal smell; all medicines, even chloroform, given by the mouth, were vomited, and enemata appeared unsuccessful. He was ordered to suck ice, and to have an aromatic poultice over the abdomen. Towards evening one-sixth of a grain of morphia, injected subcutaneously, relieved him. Abdominal collapse set in during the next two days,

and he died, perfectly conscious, without much pain, at 6.30 A.M., July 12.

At the *post mortem* examination, close to the sixth and seventh ribs on the right of the sternum, there was a small collection of pus in the subcutaneous areolar tissue, and a probe passed some distance all round with ease. There was slight effusion in the arachnoid spaces and lateral ventricles of the brain, their ependymata were somewhat turbid; in the fourth ventricle the lining was finely granular, and pale. Both right and left lungs were firmly adherent to the chest-wall. There were two cheesy masses, of the size of beans, at the apex of the right lung. There was turbid fluid in the peritoneal cavity. The upper part of the small intestine was much distended, covered with flakes of lymph; these and vegetations (granulations) were also found on the peritoneum, along with fibres and general thickening. The intestines were attached to the posterior wall by easily broken down adhesions. The distended coil (of the upper portion) of the small intestine lay at the lower part of the abdomen, partly in the pelvis; below this were three or four coils of the lower end of the ileum, which were adherent to it by its thickened, shortened, and wrinkled mesentery near the vertebral border of the latter, so that the bowel appeared much twisted in three or four places. These portions of the intestine were very thin, collapsed, softened, almost empty; and, as far as could be made out, quite pervious. The rest of the bowel, besides gas, contained thin fluid bile-tinged fecal masses, of which the upper portion of the small intestine contained more than the colon, the mucous membrane of which in many spots was dark red, and these spots showed slight loss of substance in the middle. The transverse colon and duodenum were adherent to each other very firmly at one spot, and here there was a small collection of pus. The liver, spleen and kidneys were anæmic; the former had firm adhesions; it was otherwise healthy. The thoracic vertebræ were denuded anteriorly as to their ligaments, and between them was a tolerable quantity of partly cheesy, partly purulent matter. The vertebræ themselves were small, very rough, and eroded in spots. The diagnosis was twisting of the bowel from shrinking of the mesentery, tubercular caries of the thoracic vertebræ, and pulmonary tuberculosis.

The first opinion formed of the case, that the tumour was fecal, was correct, for it vanished after a laxative. The constipation on previous occasions was probably due to previous peritonitis. The later symptoms were partly due to paralysis of a portion of the intestine. The lower part of the ileum was bent in an angular fashion in three or four spots, and here it was thin-walled and soft. The conditions for paralysis were present in the entero-peritonitis, for, according to Mayer (*Medizinische Jahrbücher*, Wien 1871, Heft ii.) and Basch (a recent communication from whom will be found in the *Wiener Med. Jahrbücher*, 1874 i.) the intestinal movements are phenomena dependent altogether upon the blood-pressure in the coats of the intestines. The vertebral column was not opened, but there were no symptoms of disease of the spinal cord during life. [The reporter thinks it possible that both the former and the latter fatal peritonitis were brought about by the actual escape of purulent and septic matters into the peritoneal cavity, of which many instances are known—then the paralysis and constipation occur as a conservative process. Useful as the castor-oil and chloroform

may be as a laxative, he cannot but think it better practice to abstain from all purgatives, when there are both pain and tenderness on pressure in abdominal attacks.—*Rep.*]

SCHMITZ ON THE ETIOLOGY OF DIABETES MELLITUS.—Dr. Richard Schmitz, of Neuenahr, writes as follows, in no. 44 of the *Berliner Klinische Wochenschrift*. He has observed and treated 104 diabetics since 1868, of which 77 were males and 27 females. The ages were as follows:—1 girl aged four years; 8 cases from ten to twenty years (including a boy aged eleven and a-half; 1 male, 1 female, aged fifteen; 2 males aged sixteen; 2 males aged seventeen; 1 female aged nineteen); 9 cases from twenty to thirty years; 16 from thirty to forty years; 16 from forty to fifty years; 38 from fifty to sixty years; 12 from sixty to seventy years; 4 cases from seventy to eighty. In 45 of these the immediate cause of the diabetes must be admitted to be some disorder of the nervous system. Of these there were many varieties; in 15, anxiety and great sorrow; in 8, intense pain, mostly due to accidents; in 7, severe affections of the nerve-centres; in 7 more there was incessant mental activity; in 3 there was great shock from fright; 3 others had practised onanism for a long time, and 2 had great nervous excitement in consequence of prurigo pudendorum. In 20 persons the diabetes might be ascribed to immoderate use of sugar; in 7, extreme debility resulting from severe illness seemed the cause; three times, severe cardiac mischief, twice bad forms of syphilis, and twice amyloid disease of the liver and kidneys were present. In the remaining 32 there was no obvious cause for the diabetes. There was albuminuria in 12 out of the 104 cases. Many of these immediate causes of diabetes, such as grief, anxiety, etc., are met with in hundreds of men, but how few of these have diabetes? One is therefore almost tempted to believe in a diabetic diathesis, or a proclivity to diabetes (disposition). This is probably inherited in many cases. Out of these 104 twenty-two showed this heredity in a marked manner. In one, the grandfather, in one, both grandfather and father; in six the father, in six mother and sister, and in eight the sisters, were diabetics. Had doubtful statements, such as 'I believe,' 'I think,' etc., been taken, the numbers would have been very much larger. Considering how few are 'posted' in family histories, and how many cases of diabetes, as Seegen says, are never diagnosed at all, we may conclude that in most cases this disease is congenital and inherited. Recognition of this proclivity may be useful to our patients.* That this diabetic diathesis, when inherited, still needs some definite proximate cause is shown by several cases. Mr. F., aged fifty-seven, lost his father from diabetes; his mother and all his sisters continued healthy. In early life he was healthy, married young, and lived steadily. Of his five children he only lost one daughter, who took her life in an attack of melancholia. The other children were healthy. This daughter's death quite shattered his health; he had jaundice, and catarrh of stomach and intestines. When these subsided he continued to lose flesh;

lost all inclination for work; thirst and polyuria set in, and four weeks after his daughter's death, his urine contained 5 per cent. of sugar. His son, aged twenty-six, was quite healthy till the year of his father's attack, when he sustained a compound fracture of the left leg, attended with much pain, by falling from his horse. Fourteen days afterwards, in addition to other symptoms, he passed urine containing 6 per cent. of sugar. These two cases are remarkable, for although one inherited the proclivity from his father, the other from father and grandfather, yet one lived fifty-seven years, the other twenty-six years, without any symptoms. The melancholia and suicide of the daughter is interesting as illustrating the relations of mental disease to diabetes. Mrs. L., aged fifty-three, has four children, all delicate. Her mother and two sisters died of diabetes mellitus, and a sister and brother suffer from it at the present time. She continued free from diabetes till her fiftieth year, when she could not sleep from prurigo of the genitals. The percentage of sugar varied from 0.2 to nearly 4 per cent. In another case, aged twenty-eight, the mother's sister, sister and niece of the patient, died from diabetes. One brother also suffers from it. [The details of these cases leave little doubt that they really were what we call diabetes mellitus. In many polyuria is expressly mentioned. It is, however, singular that the daily quantities given for the urine are by no means very excessive; being in the cases quoted fifty-six ounces, seventy-two ounces, sixty-two ounces respectively; only the last amounting to 118 ounces *per diem*. There is probably some mistake in these numbers.—*Rep.*]

OEHME ON A CASE OF INTERMITTENT CHYLURIA.—Dr. Oehme relates the case in the *Deutsches Archiv für klinische Medicin*, Band xiv. The driver of a hackney-coach, aged fifty, who suffered (as was learnt from the necropsy) from cancer of the pylorus, exhibited, besides the symptoms due to his gastric affection, the striking peculiarity that from midnight to 5 or 6 A.M., he passed an extremely white milky urine, which was in fact chyle, containing, as it did, fat and albuminous matters. This peculiarity was some time in establishing itself; at first he often passed some days without other than normal urine. The patient himself first observed this character of his nocturnal secretion at the close of the year 1872, and in consequence of extreme anorexia it ceased seven weeks before his death in August, 1874. This case is remarkable on two grounds; first, that the affection was intermittent, which has never before been described; and secondly, its subject had never been in the tropics, even for a day, which has heretofore been considered an essential element in the history of such cases.

[In Dr. Tanner's *Practice of Medicine*, 5th edit., p. 604, reference is made to some cases of chylous urine of an intermitting character, and the reporter knows of cases in which the sufferers have never been in the tropics. The disease is, however, rare in our latitudes, many cases supposed to be examples of it being instances of white lithates, with deficiency of pigment or accidental admixtures.—*Rep.*]

W. BATHURST WOODMAN, M.D.

* Thus forewarned, we may caution against too free use of sugar, too great mental activity; warn them of the dangers likely to result from injuries to the head, etc.; and if accidents have occurred, or mistakes been made, if we know this proclivity, we should at once test the urine for sugar, and then begin treatment early.

JUNKIN ON A CASE OF TRANSFUSION.—In the *Transactions of the Pennsylvania Medical Society* for 1874, Dr. J. M. Junkin reports a case in which, some years ago, he saved the life of a patient by transfusion. He says: 'I was called, about ten o'clock

at night, to see Mrs. F., and found her flooding fearfully from an abortion, at about six weeks. She was very much prostrated from loss of blood, so that the pulse could scarcely be felt at the wrist. I immediately checked the blood by a tampon of soft rags, and took all the pillows from under the head; still the prostration increased. I gave stimulants; she still continued to sink; I then raised the foot of the bed, so as to keep what blood she had in the brain, as much as possible. I continued increasing the elevation, until she had to be held, to keep from pressing against the head-board; still the pulse became more feeble, so that it could scarcely be felt at the carotid artery.

'I said there was no chance of saving her life except by giving her more blood from another person. The husband at once offered his arm; but it being far in the country, there was no possibility of getting any instruments, nor was there any time to spare, even if there had been any within reach to send for. I asked if there was a syringe in the house; one was brought, glass, female, with curved neck and a bulb on the end of it; I said it would not do; but immediately thought glass would melt, so I ran to a fire, thrust the end among the coals until it was softened, drew it out into a slender tube, broke the end off to a proper size, put it in the fire to smooth the end, then back to the patient, tied up the husband's arm and drew several ounces of blood—told him to put his finger on the orifice—filled the syringe, opened a vein in the arm of the patient, and forced as much blood as possible into the vein. Probably not more than two ounces passed; but I did not find it necessary to repeat the operation; the husband's blood was of a much richer quality, so that in a few minutes the patient began to rally, the pulse gradually coming up. By daylight I was able, by lowering a little at a time, to get the bed on a level, and in the course of a few hours to place a small pillow under the head.

'The recovery was rapid and complete. A little more than a year afterwards, I delivered the lady of a large healthy child.'

NUTT ON SPURIOUS HYDROPHOBIA.—Dr. Nutt records (*Pennsylvania Med. Soc. Report*, vol. x. 1874) an interesting case of spurious hydrophobia, confirmed by necropsy. A man, named Harry Smith, labourer, aged about thirty-five, dark complexioned, light figure, height five feet six inches, weight 125 lbs.; generally quite cheerful, but with occasional fits of depression and uncalled-for anger, while living in Elizabeth, New Jersey, was bitten by his dog in 1873. The dog was killed; and the dread of hydrophobia, with pecuniary embarrassment, excited a train of nervous symptoms that culminated in an attack of acute mania which proved fatal in forty-eight hours. On February 13 he complained of pain in his head, with pain in his hand where the indistinct outline of a scar was visible. He was wakeful, and, unfortunately, filled with terror of his impending madness; recalled the reports he had read of hydrophobia; imagined he could not drink water, and would rush back at the sight of it. But with a full dose of morphia hypodermically, he quieted down, had a comfortable sleep, but with trouble bearing heavily on him. He was rational when spoken to, but at other times wandered. He drank water with ease on the second day, and had an intense sensation of heat, which was relieved by exposure to the cold air. He died very suddenly and quietly, but his death was preceded by terrible nervous convul-

sions, which fully satisfied his attendants that it was a true case of hydrophobia. Twenty-four hours after death a necropsy was held, with the assistance of Drs. Crawford, Thomas and Edward Lyon, McVicker, and Nutt. The abdominal and thoracic viscera were normal, with some slight adhesions. The cause of death was chronic inflammation of the meninges of the brain, probably induced by a sun-stroke, two years before, while exposed in a brick-yard to the direct rays of the sun. Under ordinary circumstances, he would probably have lived an excitable life, but, with the terrible terror of hydrophobia pending, the first slight evidence of any trifling disease was confirmation doubly sure, and developed this form of mania.

HAND ON DIVISION OF THE VAGUS IN CHOLERA. Dr. H. C. Hand (*Transactions of Minnesota Medical Society*, 1874) treats of the abdominal branches of the pneumogastric nerves, and their relations to the treatment of choleraic discharges. From the quoted cases of other observers, and from his own experiments, he believes that pressure, or cold, applied over the vagi in the neck, may prove to exercise a controlling influence over Asiatic cholera, and over other abdominal troubles. Moreover, he makes the point that in desperate cases division of the nerve on one side would be good treatment—the left when emesis is the graver symptom, and the right when catharsis threatens life.

SURGERY.

GAY ON INJURIES OF THE SKULL.*—This is an article extracted from some recent American journal, the name of which is not stated; its main object is to enforce the conclusion that a blow on the head which does not fracture the skull may be considered as dangerous, or even more dangerous, than another blow which does fracture the bones. [This opinion was given in answer to a question of similar purport put to the author in a court of justice.] The speculative probability of

* *Injuries of the Skull; their Relation to Medical Evidence, with Reports of Cases and Remarks upon the Employment of the Trephine.* By C. C. F. Gay, M.D., Surgeon to the Buffalo General Hospital. 1874.

this opinion is considerable; for, if the bone be not fractured, the force may be transmitted through it to the brain below, which otherwise would be expended and brought to an equilibrium in the act of causing the fracture. But the practical importance of this doctrine does not really seem very great. No competent surgeon doubts that in head-injuries the chief danger lies, not in the injury to the bones, but in the possible lesion of the brain, and that such lesion is often found without fracture; but as a general rule we believe that blows severe enough to cause fatal mischief to the brain do fracture the skull, so that the defence which the fracture of the skull offers to the brain is certainly imperfect, and it must not be forgotten that the depression of the fracture or injury to the large vessels by fractured edges are causes of danger connected with the fracture itself. Besides, there are many other considerations which modify the prognosis, such as the age and general health of the patient, the nature of the accident, etc., and it is very difficult to estimate the force of the blow, which, it must be remembered, must be assumed to be equal in the two classes of cases compared together. For these reasons we cannot say that we attach much importance to the question treated of by Dr. Gay, considered as a medico-legal problem. Nay, we should have been ourselves disposed to give a different (though not an opposite) reply to the question stated above, viz., that a heavy blow on the head is more dangerous than a lighter one—that a heavy blow usually fractures the skull, and as, in fact, the skull, under ordinary circumstances, does not yield except to a heavy blow, it is on this account that blows on the head which cause fracture are generally more dangerous than such as do not; but that the injury to the bone is *per se* of much less importance than that to the brain (indeed is only of importance as being a possible cause of injury to the brain or its membranes), and that such injuries may be, and often are, caused by blows which do not fracture the skull. That this view of the case, though less simple for a layman, is more correct in a medical point of view than that maintained in Dr. Gay's article, seems to us to follow from the following words of the author himself.

'Any one who will, may demonstrate upon the cadaver the immense power necessary to be brought into requisition, adequate to a fracture of the cranial bones. Whosoever, I think, makes the trial, will be convinced that the impact of a force that fractures the bones of the skull must almost of necessity so confuse the brain-substance or inflict injury upon the investing membranes, or cause extravasation and blood-clot with or without fracture, as to produce, with the attendant shock, inevitable death.'

Nor does Dr. Gay make any attempt to support his conclusions by other than speculative arguments, borrowed mainly from Mr. Erichsen—and in part from another author whom he confounds with the present writer—but who is probably Mr. Prescott Hewett (in *Holmes's System of Surgery*). The cases which he recites in no way bear on the main conclusions of the paper—nor even much on the secondary one whether the trephine should not be used somewhat more freely than it now commonly is—whether it may not be justifiable in some cases to trephine in simple depressed fracture without symptoms, or even occasionally to cut down through the unbroken scalp for purposes of diagnosis. One

case indeed is given (Case 6) in which a supposed depression of the skull was found, on cutting down on it, to be imaginary, due we presume to extravasation; but it has little bearing on the surgery of head-injuries, since the patient died from other causes.

On the whole, though personally inclined to agree with Dr. Gay to a great extent on both the subjects of his paper, we cannot say that he has done much to prove either.

T. HOLMES.

BEDOIN ON URETHRITIS.—Dr. Bedoin, chief surgeon in the military hospital of Versailles, employs both liquid and solid injections against urethritis. The formula of the liquid injection is as follows:—Crystallised sulphate of zinc, crystallised subacetate of lead, of each 20 centigrammes; distilled water, 100,00 grammes. The bottle to be shaken whenever the injection is used. According to the *Annales de la Société Médico-Chirurgicale de Lille*, October, 1874, as soon as the inflammatory period is passed, Dr. Bedoin gives his patients four or five injections daily. In proportion as the discharge diminished, he reduced the injections first to three, then to two, then to one, and proceeded in the same way until there was not the slightest urethral discharge. Towards the conclusion of the disease he gave the patients a little wine, and gradually augmented the quantity until the urethritis was completely cured. The solid injections were administered according to Dr. Paillasson's formula; they consisted of simple glycerole of starch, or with a hundredth part of sulphate of zinc added to it. To insert these solid injections into the urethral canal, Dr. Paillasson uses a cylindrical or flexible tube, like those in which painters keep their colours, previously filled with glycerole of starch. A small cannula is screwed to one end, and gradual pressure, exercised at the other by means of a small key round which the tube is rolled, forces the injection into the urethra. The tube is graduated into equal divisions, which serve to indicate the average dose of the drug to be injected into the canal. Both chemically and physically the glycerole generally used by M. Paillasson is extremely well adapted to remain in the urethra, and the operation is absolutely painless in the immense majority of cases. These methods of treatment have been tried for six weeks on seventy-two patients, the minimum duration of the treatment having been from ten to fifteen days.

The results obtained were fifteen failures, of which eleven were treated by liquid injections, and two by Dr. Paillasson's solid injections. The cures amounted to fifty-nine, of which forty-five, one case of acute, and eight of chronic urethritis, were healed by liquid injections, and six were treated by Dr. Paillasson's solid injections.

TURNIPSEED ON REMOVAL OF A KNIFE-BLADE FROM THE HEAD.—Dr. E. B. Turnipseed (*Transactions of the South Carolina Medical Society*) gives an account of the removal of a knife-blade from the head of a negro man, after remaining for three years imbedded in the anterior left lobe of the brain. He had been stabbed in a quarrel, but had no certain proof that the blade was left in the wound. Epileptic convulsions soon appeared, and continued with great though variable frequency. His condition was so very bad, that Dr. Turnipseed resolved to expose the slight bony swelling which marked the wound, and, if nothing were found, then to trephine. The blade was discovered very readily and removed.

No further interference was judged to be advisable. The piece of steel was one and a quarter inches long, one inch having been in contact with the brain. Convulsions have since occurred, but with diminished frequency.

MATERIA MEDICA AND THERAPEUTICS.

CERASI ON THE THERAPEUTIC USES OF PROPYLAMINE AND ITS SALTS IN VARIOUS DISEASES. Dr. Philippo Cerasi, in a work recently published by him, affirms that this drug is not poisonous when it is given in suitable doses (from nine to forty-five grains *per diem*.) He fortifies his opinions by the experiments of M. Raynal and Dr. Dujardin-Beaumetz, and adds that in his practice he has always found a difference of action between the chlorhydrate of trimethylamine and the chlorhydrate of amylamine. The former rather possesses a sedative action on the nervous system, and the second diminishes the temperature more rapidly by regulating the circulation. He also observes that all the salts of propylamine have a more or less rapid and marked action on the nervous and cardio-vascular system. He has successfully employed propylamine and its derivatives in fourteen cases of acute rheumatism. In three cases the patients showed well marked cardiac symptoms, intense dyspnoea, very painful precordial pain, and small pulse; all these morbid phenomena gave way rapidly to the action of the drug. Dr. Cerasi mentions that in one case where the pains in the joints persisted, he used propylamine as an external application with much success. He had the painful joints rubbed with a liniment composed of one part of propylamine in three parts of glycerine, over which a layer of wadding was laid. This is a fact of some importance.

Dr. Cerasi having made up his mind from these experiments that this drug has a salutary action on rheumatism, by the depressant power it exercises on the cardiac activity and arterial dilatation, and by its narcotic powers, in order to determine if these therapeutic qualities were really present, has tried analogous experiments in other diseases, and he has begun to use it in affections in which it is necessary to moderate and regulate the circulation of the blood. He prescribed chlorhydrate of trimethylamine for four patients suffering from imperfect cardiac innervation, and it succeeded in

calming the heart's action with sufficient quickness. He also had reason to be satisfied with its use in two cases of hypertrophy, and one of cardiac dilatation. In a case of acute pericarditis, this drug diminished the pain and lessened the force of the pulsations; whilst in two cases of catarrhic pneumonia, and in one of amygdalitis accompanied by fever, propylamine had advantageous effects. Dr. Cerasi thinks that if ulterior observations, taken on a large scale, should serve to confirm the fact that this agent, which moderates the excess of caloric, can arrest the morbid processes in which profound organic oxidation is the great cause of the regressive organic metamorphoses, the practitioner would possess a precious means of gaining time and combating disease with greater certainty.

Pursuing his researches, Dr. Cerasi made experiments with propylamine, administered in cases of infectious disease. In two cases of typhoid fever, and in one case of typhus, he found the temperature lowered by the use of this medicine. In two cases of pyæmia, the propylamine lowered the temperature progressively; but in one of them the temperature, having fallen to 37°, suddenly rose to 40°, and the patient died. He obtained a notable lowering of the temperature in two cases of scarlatina, and in one of malignant small-pox during the suppurative stage. He made use of it in a case of acute alcoholism, accompanied by a very high temperature, which is a serious symptom; the first day it was 38.2° Cent. (100.76° Fahr.), the second 39.5° Cent. (102° Fahr.), the third day over 40° Cent. (104° Fahr.). It was then that chlorhydrate of amylamine was administered, and at the end of two days the temperature had fallen two degrees. The same plan of treatment was persevered in, and on the fifth day the temperature fell to 38°, and on the ninth day it was at 37.2°.

From these results, Dr. Cerasi concludes that propylamine and its derivatives exercise a depressing action on the cardio-vascular circulation, and that this action appeared to him to reside in a certain elective action on the heart and the tonicity of the arterial vessels. It also diminishes the excess of heat produced by certain morbid processes, especially in those caused by the presence of ferments. It brings the peripheric circulation into harmony with the central circulation, especially when the defective distribution of the blood is caused by disturbed innervation. Dr. Cerasi winds up by requesting medical practitioners to verify whether propylamine possesses the properties which he attributes to it.

WAGGONER ON THE USE OF ALKALIES.—Dr. Waggoner (*Transactions of the Medical Society of the State of Pennsylvania*, no. 10, 1874) writes: 'Since I entered the practice of medicine, twenty-five years ago, I have had trouble with the iodides. Many stomachs will not tolerate them; and, moreover, my patients were complaining of enteric flatulence, and the bad smell of all the emanations from the body. I speak, also, from personal experience. As a substitute, I have been using the alkaline carbonates and bicarbonates, with good success, and more satisfaction to my patients. Those who were troubled with glandular enlargements and indolent ulcers, and whom I had treated with iodide of potassium as the *sine qua non*, are now relieved quite as promptly by bicarbonate and carbonate of potassa and soda. I think we made a mistake when we accredited the

cure to the iodine instead of the alkali. I give this as the result of observation and experience, and also because it was Professor Nathaniel Chapman's favourite remedy. He used salt of tartar or carbonate of potassa.⁷

BLAND ON THE TREATMENT OF SCARLATINA BY HYPOSULPHITES AND CARBOLIC ACID.—Dr. Bland says (*Transactions of the Medical Society of the State of Pennsylvania*): 'In the treatment of scarlatina anginosa, I must again renew my indorsement of the internal administration of the hyposulphites and carbolic acid. The results obtained in this disease with the above remedies are unprecedented, and give every evidence to warrant their continued use. I recently treated seven cases in one family, four of whom had severe throat-ulcerations. The topical application of carbolic acid and glycerin to the inside of the throat, the hyposulphite of soda internally with good nutritious diet and febrifuge mixture as required, was the treatment employed, and in eight days the patients were all well. A number of my colleagues have tried the foregoing remedies, and give them their unqualified endorsement.'

OBSTETRICS AND GYNÆCOLOGY.

PANAS ON THE ULTIMATE RESULTS OF OVARIOTOMY.—M. Panas (*La France Médicale*) in a paper read before the Société de Chirurgie, on June 3, 1874, says that up to the present time only one thing has been taken into account, whether the patient can be operated on or not; or rather, is an operation feasible? M. Panas says that an ovarian cyst may be removed by operation, but in some cases the surgeon ought not to operate because of the nature of the tumour. Tumours appearing simply cystic may return in a year or two after the operation.

For example, a woman operated on at St. Louis, in 1871, had an ovarian cyst and subperitoneal fibroid removed. The cure was rapid. The following year the patient re-entered the hospital in a deplorable state; the glands of the groin, breasts, and clavicular regions being invaded by cancer. And yet the tumour removed appeared to be an ordinary cyst, with nothing cancerous about it.

Last year M. Panas tapped a woman having several cysts of the ovary, and drew off eighteen litres of fluid. The tumour had grown in eight months. Vaginal examination revealed a cancrroid of the cervix. The patient is now dying with cancerous cachexia.

There are, then, cysts of slow growth and cysts which grow rapidly; these last he regards as malignant, and likely to return after ovariectomy.

[This may be all very true, but Mr. Spencer Wells's extensive statistics of all sorts of cases show recurrence to be rare; and even if it may happen, and the tumour can be removed, surely the operation is as justifiable as the removal of any malignant growth. In the case quoted above, the affection of the cervix by no means proves that the ovarian tumour was a malignant one also.—*Rep.*]

MACDONALD ON OCCIPITO-POSTERIOR POSITIONS OF THE HEAD.—Dr. Angus Macdonald (*The Edinburgh Medical Journal*, October, 1874) as the result of an analysis of twenty-six operative cases, has arrived at the following conclusions.

1. In occipito-posterior positions, if these be persistent, we may safely assume that we have some pelvic peculiarity or disproportionately large head to deal with, and, as a general rule, all attempts at artificial rectification of the position of the head will prove abortive, and are even dangerous if attempted to be effected by means of levers, forceps, etc.

2. The only exception is when temporary delay is occasioned from accidental displacement of a small head; in which case one has the alternative of waiting till the normal powers of parturition effect delivery, or of facilitating that event by timely rectification of the head by the hand.

3. In cases which threaten to end as 'face to pubes,' and are at the same time decidedly difficult, it is best to pull the head through cautiously, and to abstain from every attempt at rectification of the head,—special care being taken to guard the perinæum, as the occiput, when passing over it, greatly distends it.

4. In cases of obstructed occipito-posterior positions, in which the rotation takes place at the outlet of the bony pelvis, while the head is in the grasp of the curved forceps, there is very great danger in the case of primiparæ of the forceps lacerating the soft parts, on account of the oblique position into which they are thrown.

5. To prevent this accident, either—(i.) the blades ought to be cautiously removed, the head fixed in position, and the uterus allowed to finish the expulsion of the head; or, (ii.) the curved instruments may be reapplied, adjusted to the altered relation of parts; or (iii.) a straight short pair may be applied, and the further advance of the head thereby secured.

AUGER ON DERMOID CYST OF THE BROAD LIGAMENT: GASTROTOMY AND CURE.—A girl aged eighteen, a virgin, entered in February, 1871, the Hospital Saint-Antoine. She had suffered for two months violent pains in the flanks and loins with obstinate constipation. There was no menstrual disorder. The abdomen was very painful, and there was dysuria. M. Leroy diagnosed an abdominal tumour, which he aspirated, and drew off a quantity of thick, fatty, yellow matter, in which the microscope showed epithelial cells, like those found in the sebaceous glands.

The os could not be reached by vaginal examination, but there was a hard tumour filling up both the back and front parts of the pelvis, with a fold in the vaginal mucous membrane between the bladder and rectum, both being pressed upon. The tumour reached to the umbilicus. She suffered so much that an immediate operation was desired, and M. Auger operated and removed a dermoid cyst from between the folds of the broad ligament. It was very closely adherent to the body of the uterus, but had no proper pedicle. The Fallopian tube passed over the upper part of the tumour. The ovary was not seen. The tumour was on the right side.

[This is an interesting case, as the tumour corresponded in all its anatomical relations with the extra-ovarian cysts, which are affirmed by some to be always unilocular, and derived from the organ of Rosenmüller. Here, on the contrary, there was a cyst evidently of ovarian origin, growing between the folds of the broad ligament, and with the tube stretching over it. The case would be more interesting if the ovary, or any remains of it, had been seen. Was the tumour the result of an ovum

escaped between the layers of the broad ligament, or of a Graafian follicle in the same situation? If not, whence its dermoid nature?—*Rep.*

J. KNOWSLEY THORNTON.

VON GRUNEWALDT ON STERILITY ATTENDING DISEASE OF THE SEXUAL ORGANS.—At the Congress of German Naturalists and Medical Men, held in 1874 at Breslau, in the gynecological section (*Berliner Klinische Wochenschrift*, November 23, 1874), Dr. Von Grunewaldt, of St. Petersburg, discoursed on the sterility of women, with diseased sexual organs. He found that out of 824 sick women of the age and under circumstances favourable for impregnation, 432, or more than fifty per cent., were sterile. He came to the following conclusions. 1. Sterility of women is a disturbance of the normal function of the sexual apparatus. 2. Conception forms only one link in the course of events by which the female provides for the propagation of the species. 3. A complete mechanical impediment to conception of the woman arises only in consequence of atresia in the course of the genital tract. 4. The point of difficulty in propagative activity in the woman, as far as the uterus is concerned, rests on the capability of the impregnated ovum for germination (*Bebrütung*.) 5. This capability depends exclusively on a certain degree of integrity of the consequent tissue of the uterus. 6. The part which ovulation plays in the process of propagation can be defined clinically, only rarely, or not at all.

LEOPOLD ON THE UTERINE LYMPHATICS.—Dr. Leopold of Leipsic (*ibid.*) made a communication on the lymphatics of the gravid uterus and of the secundines. He found that the uterine mucous membrane exhibits a vast lacunar and cavernous system of lymphatic spaces; the latter surround the blood-vessels and uterine glands, and are to be viewed as the beginnings of the lymph-tracts of the whole uterus; they pass through from the mucous membrane to the cellular tissue covering the uterus (*Parametrien*) and here, as large valved spaces, enter the pelvic lymphatic glands. The mucous membrane of the pregnant uterus displays the same lymph-spaces, but in greater number and of a greater calibre. The effect of this is that, when after an abortion or labour the placenta is thrown off, the small remainder of the mucous membrane of the puerperal uterus consists of thousands of patulous lymph-spaces. This explains the possibility of very rapid absorption of septic materials conveyed into the vagina or uterus. Not only is the maternal placenta, but also the membranes, are permeated with lymph-spaces, particularly the amnion, which is constituted like peritoneum, and whose inner surface may be represented as a lymph-sac.

SCHATZ ON THE LIQUOR AMNII.—Professor Schatz, of Rostock (*ibid.*) spoke on the question of the source of the liquor amnii. He found that a large part, if not the larger portion, of the amniotic fluid was yielded by the kidneys and the skin. The chemical constitution of the fluid proved this. Its interchange, viz., its constant reabsorption and its reappearance in urine and sweat, seemed to proceed very actively. The consistence of the meconium admitted of the conclusion that the foetus, during the last months of gestation, partially swallowed its liquor amnii. This the author proved by an observation made in a case of twins.

LANDAU ON THE ORIGIN OF URINARY FISTULÆ IN WOMEN.—Landau of Breslau (*ibid.*) spoke on the genesis of urinary fistulæ in women. He blamed the forceps as the chief cause of fistulæ situated in the lower portion of the vagina and of complicated ones, not so much by the production of sloughing by their blades, as by pressing the back of the head against the anterior pelvic walls and increasing friction. For the formation of fistulæ situated higher up, the pressure of parturition alone sufficed as the direct cause.

FRÄNKEL ON THE TREATMENT OF SPASM OF THE UTERUS.—Dr. Fränkel of Breslau (*ibid.*) related a new method of treatment of spasm of the uterus during expulsion of the child and placenta. When the uterus has become completely or partially spasmodically contracted on the foetus, or on a separated placenta, which in the former case is frequently the result of the liquor amnii draining away in cross-births, and preventing the passage of the hand to turn the child, he proposes to overcome the spasm by injecting hypodermically a solution of sulphate of atropine (0.001 gramme = $\frac{3}{100}$ grain) and of muriate of morphia (0.015 gramme = about $\frac{1}{4}$ grain), with inhalation of chloroform about five minutes later. There is no fear of *post partum hæmorrhage*; the uterus relaxes speedily and yieldingly.

W. C. GRIGG, M.D.

NEW INVENTIONS.

SOLID THIRST-QUENCHERS, OR EFFERVESCING LOZENGES.

At the annual *conversazione* of the Harveian Society, we had an opportunity of examining these medicinal novelties. They are, no doubt, what they profess to be, 'Thirst-quenchers,' for, immediately they are placed on the tongue they begin to effervesce, stimulating the buccal and salivary glands, thus relieving the desire for drink. They are as agreeable to taste as they are elegant in form; and we can readily understand that they have in a high degree the power of allaying sickness and fever. To the frequenters of theatres, concerts, and places of amusement, they afford a ready means of quenching thirst; to the pedestrian and railway traveller they offer still greater advantages. The inventor has, besides meeting a great public want, applied the process by which they are manufactured to the more agreeable and efficacious mode of administering medicines, a few of which will give the medicine-taking public some idea of the variety of forms under which medicine may be presented to them. The 'Effervescing Astringent Voice Lozenges' are particularly applicable to the use of public speakers, singers, and actors. These contain an alcoholic extract of eucalyptus or red gum, which is deposited on the uvula and back of the throat, acting as an astringent on those parts, without drying them. They are largely used by the principal operatic singers and by the clergy, for whom, it is said, they are prescribed by the highest medical authorities. The effervescing ipecacuanha lozenges rapidly relieve the huskiness arising from a cold. 'A tonic effervescing lozenge,' containing four grains of saccharated carbonate of iron attracted our attention. Besides the facilities afforded to gentlemen for taking their doses in the counting-

house or public courts, without asking for a glass of water to wash down the nauseous pill, or a glass to take a dose of 'the mixture,' it struck us that the iron frames of our soldiers may be further strengthened by use, when on the march, of these lozenges. A lozenge containing bismuth and soda is worth the notice of those who suffer from indigestion. A large variety of the effervescing lozenges are kept in stock by the maker.

MISCELLANY.

THE TREATMENT OF STAMMERING.—The Prefect of the Seine having consulted the French Academy of Medicine on the relative merits of the methods of treatment for this affection respectively recommended by MM. Colombat and Chervin, the Academy appointed a commission to inquire into the subject. This commission states that M. Colombat's plan, which was reported on favourably in 1830, continues to afford favourable results which are confirmed by the experience of years, and that it is therefore worthy of adoption by the authorities.

PUBLIC LIBRARIES OF PARIS.—An article has just been published in the *Bibliographie de la France* in answer to the statement made in the Assembly by M. Laboulaye, that the great schools of Paris are almost destitute of libraries. We learn from it that the École de Médecine possesses a library of 32,000 volumes, well cared for, and placed in a handsome room, capable of seating as many as 150 readers at a time. Adjoining it is the celebrated anatomical collection, known as the 'Musée Orfila,' occupying a suite of six rooms. Many of the other technological schools of Paris also have good, in some cases, large libraries, so that it would appear that M. Laboulaye was not altogether accurate in his statements.

ENCOURAGEMENT TO SCIENCE.—Amongst the grants made by the Royal Society from its Donation Fund is one of 100*l.* to Dr. Dohen, in support of the Stagione Zoologica at Naples, in which Mr. Ray Lankester and Mr. Balfour have recently made a series of observations on marine animals. One hundred pounds from the government grant of 1,000*l. per annum* has been appropriated to Dr. Klein's work on the Anatomy of the Lymphatic System. With regard to the Ponti will, in which the late Signor Ponti bequeathed a portion of his property to the 'Academy of Science of London'; as it does not appear what Society is indicated under this title, and as the relatives of the testator intend to dispute the will, the Council of the Royal Society, as at present advised, will take no steps in the matter.

THE PRIZES OF THE FRENCH ACADEMY OF SCIENCES.—At the annual public meeting of the Paris Academy of Sciences, the medical and scientific prizes were awarded as follows:—The Montyon Prizes of 2,000 francs, for the year 1872, to Dr. Luys for his Photographic Iconography of the Nervous Centres; to Dr. Magnan, for his researches on the Comparative Action of Alcohol and the Essence of Absinthe on the Nervous System of Man and Animals; and to Dr. Woillez, for his clinical treatise on the Acute Diseases of the Respiratory Organs. Honourable mention, with a gratification of 1,200 francs, to Dr. Mandl, for his practical treatise on the Diseases of the Larynx and Pharynx; to Dr. Fano, for his treatise on Ophthalmology; to M. Legrand de Saulle, for his work on the Hallucination of Persecution. Honourable mentions to Dr. Bonnafont for his treatise on Diseases of the Ear and memoirs on the Transmission of Sonorous Waves, etc.; to M. Lebon, for his investigations into the Nature and Amount of the Principles of the Tobacco-Smoke absorbed by Smokers, and the Effects produced by them; to Dr. Liouville, for his treatise on the Generalisation of Miliary Aneurisms; to Dr. Bourdillat, for his work on Urethral Calculi; to Dr. Gimbert, for his memoir on Eucalyptus;

to Dr. Lisle, for his clinical lectures on Mental Diseases; to Dr. Paslin, for his work on Gunshot Wounds; to Dr. E. Ritter, for his work on the Modification of the Secretions under the Influence of some Agents which Modify the Blood-Corpuscles. One of the prizes of 2,000 francs, for 1873, was awarded to M. J. Péan, for his work on the Partial or Total Ablation of the Uterus by Gastrotomy; Certificates and 1,200 francs to Dr. P. Bouland, for his Anatomical Investigations into the Normal Curvatures of the Spine in the Human Subject; and to Dr. Oré, for Intravenous Injections of Chloral. Honourable mentions to MM. Bergeret and Mayençon, for investigations into the Metals in the Tissues and Humours by the Electrolytic Method; to MM. Louis and Ernest Bremond, for their work on Cutaneous Absorption; to M. Burdel, for his work on Cancer considered as of Tuberculous Origin; to M. G. Felizet, with 500 francs, for his Anatomical and Experimental Investigations on Fractures of the Skull; to MM. Hardy and Montmoja, for a Photographic Clinical Work on Skin-Diseases; to M. Lefevre for his Hygiene and Therapeutics of Sweating induced by Vapour Baths, etc.; to Dr. Lunier for his work on the Progressive Increase in the Number of Lunatics and of its Cause, and on the part played by Alcoholic Drinks in the Increase of the Number of Cases of Mania and Suicide; to M. Ferd. Monoyer for his Memoir on Ophthalmology; to M. Auguste Ollivier, with 500 francs, for his work on Puerperal Pathology; to MM. Polaillon and Carville for their work on the toxic effects of Inea, a Pahonin poison; and, with 500 francs, to M. P. Bédard for his Clinical Thermometry. The Brant prizes of 3,000 francs for the year 1872, were awarded to Dr. J. J. Bouley (deceased) and to Dr. Robbe. To M. Metter were awarded 200 francs. The same prizes for 1873 were awarded as follows:—2,500 francs to Dr. Proust and 2,500 francs to Dr. A. Pellarin. The Godard prize for 1872 was awarded to Dr. Pettigrew of Edinburgh, for his work on the Muscular System of the Bladder and the Prostate Gland, and on the Mechanism of the Occlusion of the Urethra and the Ureters. The Montyon prize of 764 francs for Experimental Physiology was awarded to M. Georges Pouchet, for his work on Changes in Colour in certain Animals under the Influence of the Nervous System. The Lacaze prize of 10,000 francs, which was awarded for the first time, was given to M. Marey, and honourable mention to M. Bert.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 1*7s.* 4*d.*; free by post, 1*9s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 1*9s.* 6*d.* Cloth Cases for binding the Numbers for each year may be had for 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, JANUARY 20, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE FORMATION AND TRANSFORMATION OF BONE. BY PROFESSOR R. VIRCHOW.*

In performing my duty towards the society, I have selected a subject with which you are tolerably conversant, in consequence of various important debates and communications, but which, nevertheless, in its relation to pathology and practical medicine, presents many points of view which have not yet been sufficiently treated. It will, moreover, be interesting to you to have an opinion expressed *a non irato*, especially by one who for a long series of years has followed the changes of doctrine, and has personally been a fellow-worker therein.

Both of the most important points which in recent years have come into the foreground, have here received the most weighty consideration on both sides. I refer, on the one hand, to the question as to the internal arrangement of bone, especially the structure of the spongy substance; and, on the other hand, to the question of the process of absorption on the surface and in the interior of bone, especially the relation thereto of the giant-cells (myeloplaxes, osteoclasts). Both questions have been brought before you from the beginning by Herr Wolff and Herr Wegner. But, as is the case in the history of science, questions of this kind arouse anew a whole host of inquiries from their slumber in the bosom of science. Yes, it is a surprising spectacle, to see how a whole series of questions comes anew into play, of which I have already seen the cycle completed, and which I imagined to be definitely settled. I find, when I look back on my experience in these contests, a difficulty of no small magnitude, not merely affecting the younger generation, in the circumstance that terminology is constantly changing, that subjects which were known under certain names become suddenly unrecognised in consequence of the new names given to them, and that a department over which one had had a tolerably distinct survey, suddenly comes under observation as if through a clouded window, so that one is not sure that he understands what he sees.

There is scarcely a single subject in science which has presented in so marked a manner this change of perception in the period of time which I embrace within my personal recollection, as the doctrine of the medulla of bones. And although, at first sight, neither the osteoclasts nor the formation of the spongy substance have anything to do with the matter, allow me first to say a word or two regarding them. At the time when I myself entered the scientific world, Bichat's view still prevailed, according to which it was imagined that the medullary

cavity existed in the interior of bones as a true cavity, which, according to the *à priori* position of Bichat must be lined with a special membrane, endosteum or medullary membrane. Thus the interior of bones was looked on as a series of serous cavities; for the medullary spaces also were regarded in the same light as the medullary canal. For a long time the influence of this purely *à priori* assumption was maintained in medical language, and especially in pathology; and the greatest difficulty in determining accurately the relation of the marrow, lay in the fact that most men could not get rid of the idea of the 'medullary membrane.' From the moment when histological research was undertaken, we arrived at the opposite idea, that there is in fact no cavity, and that the appearance of such is only found in macerated bones. We very soon discovered that the fault of the old view lay in the circumstance that it was not found in the examination of normal and diseased bones, but of macerated bones. We found, that in place of the cavity of the macerated bone there was in the living or recently dead body a connected tissue: that the bone thus exhibited a continuity of tissue presenting only certain differences in individual sections, differences, indeed, of such a magnitude that it was then not yet quite possible to find a sufficient average type, inasmuch as the inner connection of these forms of tissue was as yet concealed from us. But after we knew that these cavities are full of a connective tissue, after the name medullary tissue (*tela medullaris*) came into use, the idea at once arose that it was an exceptional kind of tissue, as much a special structure as cartilage or bone is, a tissue to be recognised by certain characteristics, and having its own special place among the other tissues. If you look through the publications of the last fifty years, the *tela medullaris* constantly meets you in this state of special existence; and perhaps all of us are not entirely blameless of allowing such an idea to take root. I have personally endeavoured to change this idea, and to adduce evidence that the medulla does not only correspond with other tissues, but that there is in it a certain variability, so that altogether different forms of medullary tissue exist at the same points at different times, even under conditions which we call physiological, and at the part, where at an earlier period we recognised a certain tissue, we find later a quite different tissue (See *Cellular Pathology*, 4th edition.) Thus also in like manner it became evident on the other hand, that in different bones of the same body, in the physiological condition, so great differences existed simultaneously in the medulla, that it was impossible to draw up from any one part a schema that would be applicable to another part. It became evident that at least three different conditions of tissue had to be distinguished one from another; red marrow, yellow marrow, and gelatiniform marrow.

Of these three kinds of medulla, that which has been longest recognised is the yellow or fatty marrow. It is this of which pommades are made; it is this which Clopton Havers made the special object of his researches, the lobules of which he regarded as glands; it is this which is found in all tubular bones in the adult. It can with the greatest ease, according to modern histological knowledge, be ranged by the side of adipose tissue. It differs from the fatty tissue of the panniculus adiposus in nothing but in being of less firm consistence; it is more readily broken up. Considered histologically, it is just the same

* Read before the Berlin Medical Society, November 25, 1874. (*Berliner Klinische Wochenschrift*, January 4 and 11.)

thing as the panniculus adiposus. This yellow or fatty marrow becomes changed under manifold conditions into gelatiniform marrow, a substance which, when present in a certain state of completeness, is represented by only one structure in the human body—the vitreous body. The earlier idea of this was, that it was only a fluid (*humor*) secreted by the hyaloid membrane. For us, it is a solid tissue, and it most nearly approximates to the gelatiniform medulla. I have classed the tissue of the vitreous body with mucous tissue, because mucin is found in the intercellular substance. I must, however, remark that, in spite of the great similarity, this classification does not altogether hold good for yellow medulla, in so far as this manifests itself as a diverging variety, in which the mucus falls into the background, and the foreground is occupied by albuminates, the nature of which is not yet sufficiently known, but which resemble paralbumin.

When ordinary yellow medulla becomes changed into this gelatiniform marrow, the following is what takes place. While, in the yellow medulla, the fat-cells lie closely pressed together, so that on making a section we can scarcely see a pair of vessels ramifying between them, we find that in the gelatiniform tissue the cells become small, and that there are spaces between them. The cells lie further apart; the fat no longer fills them completely. Usually single drops only are found in them, in many cases nothing more. The simple cellular form of the fat-cells is also in some degree altered. On the other hand, there becomes collected in the intercellular spaces a quite soft substance, like the vitreous humour, which is in fact the principal constituent of the gelatiniform medulla. The difference from fatty tissue is thus indeed great. While in the latter the large cells constitute nearly the whole of the tissue, in the gelatiniform tissue the intercellular substance assumes large dimensions. Herewith the mass assumes a soft, compressible, diffuent character; a character which our veterinarians have quite rightly designated by the name of medullary fluidity (*Markflüssigkeit*). As the opportunity of seeing this kind of marrow is not very frequent, I have brought with me a fresh bone which shows this condition very well. It is a longitudinal section of a femur: the whole mass of the marrow trembles like jelly. In this marrow the vessels are preserved, many of which can be seen with the naked eye; and (a fact to which I will call special attention with reference to this case) in consequence of the extraordinary softness of the tissue, hæmorrhagic effusions very readily take place into its substance, whereby greater or smaller parts of the mass become permeated with blood, so that, as you see here, in the upper section of the thigh-bone, a dark red appearance is produced, which, however, does not indicate the condition which is called red medulla. It is not everything which appears red that is red marrow in the sense in which I use the term. It is the gelatiniform marrow which almost always accompanies osteomalacia; and even in this case we should perhaps be justified in speaking of osteomalacia, in so far as, within the gelatiniform region, microscopic examination shows a direct melting down of the trabeculæ of the bone into fibrous shreds. The individual from whom the bone was taken was in a strongly marked state of syphilitic cachexia, and the local process in the marrow is an atrophic manifestation which we may class along with the so-called yellow osteomalacia.

Different from both these kinds of marrow is the

red marrow, which, physiologically, we meet with as the commencement of the formation of medulla, which occurs in its greatest extent in children in the bones, even in the long bones; but which in adults is found in those bones which consist chiefly of spongy substance, and have no special medullary cavity, such as the bones of the vertebrae, the bones of the base of the skull, the ribs and sternum, and a great part of the pelvic bones. These bones, throughout the whole of life, show conditions of marrow which never pass into complete yellow medulla. The distinguishing characteristic of this third variety is, that the cellular structure predominates. In this respect it resembles yellow medulla in so far as very little intercellular substance is present; but the cells, which are mostly round, lie very close, and between them ramify numerous vessels of wide calibre, giving the tissue its red appearance. To a certain extent this may be called young marrow; but as it is persistent in many parts, the appellation is not altogether applicable. In any case its position with regard to the two other kinds of medulla may be thus defined: that it passes into yellow medulla by enlargement of its cells and by assumption of fat, and into gelatiniform marrow by the extension of the intercellular substance, which widens the spaces between the cells. A relatively much greater amount of yellow or gelatiniform marrow may arise from a mass of red marrow; and on the other hand, the transformation of yellow or gelatiniform medulla into red is not possible without a numerical increase of the cellular elements. This takes place in general by a process which is connected with the multiplication of existing cells, and is called into activity by irritation.

I lay stress on these conditions, which perhaps are well known to you, because, on looking through the most recent literature of the development of bone, just at the point where ossification takes place, I meet with the assertion that new bone-tissue originates from medulla. Even in the points in which I imagined that I had established some amount of certainty by my researches, e.g., in regard to the development of bone from periosteum, where some years ago I had the pleasure of finding that the most eminent histologists acknowledged that my position was correct, it is now said, 'the bone-tissue arises from marrow.' When it is asked how the development of new vascular canals takes place in the midst of cartilage, the answer still is—all originates from marrow. I do not at all understand what this means. If marrow is in itself a variable tissue (a *Wechselgewebe*, as I am accustomed to say) which is quite different at different times, the cells of which in different circumstances behave quite differently with regard to their size and arrangement, and to the special peculiarities of their physiological function, I know not what is meant when the assertion is instantly repeated—they are medullary cells. Young undeveloped cells are apparently indifferent cells; they have nothing characteristic in themselves, so that one falls into the difficulty of confounding them with other young or indifferent cells. This is also the case with the red marrow. It, therefore, seems to me that error must arise from the extension at will of a recognised terminology to a territory to which the tissues of which we speak do not at all belong. It is my opinion that, since marrow is in itself a variable tissue, possessing no special peculiarities, but rather finding in its various conditions its analogies in various parts; a tissue which, according to its dif-

ferent conditions, must be brought into a distinct category of forms of tissue, the expression 'marrow' ought not to be used further than as a territorial (topographic) one, *i.e.* for those parts where within the limits of a bone (including the cartilage) a soft physiological tissue is developed, differing from cartilage, from bone, and from the periosteal connective tissue, but yet belonging to the group of connective substances. That only is marrow; and we will call the space in which it is contained a medullary space or medullary cavity, assuming that it is not a heterologous pathological tissue.

This 'inner' tissue is the youngest son of a common mother or mothers, of which the bone, as a whole, with its individual component tissues, is the offspring. At first there is no marrow; it is the last tissue which is formed; and it indicates the completion of the bone. Whence comes this tissue? On this there have been long and numerous differences; and I fear that we have not yet arrived at the resting point. In my opinion, the marrow, arises from both the principal tissues which form the substance of bone—either cartilage or osseous tissue. Whether the periosteum can form marrow I am not certain. If a tissue be produced from periosteum, which resembles young red medulla, I have never seen yellow or gelatiniform marrow produced from the tissue, nor have I ever seen it remain as red marrow. If a mass of young tissue with indifferent cells be found on the surface of a bone, I do not know on what grounds this substance should be called marrow.

As regards, on the other hand, the transformation of cartilage into marrow, this is a matter which I imagined that I had settled a quarter of a century ago in my memoir on rachitis. I must still, to-day, hold to the opinion that cartilage can be directly transformed into marrow; and although some observers of the most recent time have put forth very different opinions, I am still not convinced of the correctness of their opinions. It will, perhaps, be said with regard to rachitis, that it is a pathological case. In reply to this, I remark: This is an erroneous objection. Pathological cases are very fitted for establishing physiological laws. I know no example of a case in which a process which occurs pathologically may not also take place physiologically; the difference lies only in that the locality, the extent, and the special circumstances under which the process occurs, are different. But the *modus procedendi* remains the same. Examples are found where a medullary cavity, filled with yellow adipose tissue, has been formed in the costal cartilage, in its axis, apart from all surfaces. In some circumstances, indeed, it is seen that the cartilage-cells take up fat; and this they do not in small quantities, but they are seen to enlarge and grow visibly, and, while they yet remain in the substance of the cartilage, they contain fat. Then the substance of the cartilage around them becomes soft; and thus the medullary space in the cartilage increases through a new growth of fatty marrow. The transition from one condition to the other, from cartilage to fatty tissue, can be observed to take place directly, without any intervening stage.

It is now said, indeed, that in the formation of bone from cartilage, the new vessels, which are formed in the cartilage from without inwards, are pushed in from the perichondrium, and carry with them a certain quantity of 'marrow-cells,' which they have formed on the inner layer of the perichondrium,

and which they push before them deeply into the cartilage. I have very closely studied the development of these papilliform vascular tufts, very much resembling the villi of the chorion, which sink perpendicularly into the cartilage and which usually precede ossification; and I am of opinion that there is no pushing in of elements from without, but that the new elements are formed by metaplasia from the cartilage-cells. Even Kölliker has lately asserted that a pushing inwards takes place. In spite of this, I regard as correct the position, that a direct transformation takes place within bone, and that quite similar deposits take place in cartilage at a distance from the surface, which show in the most distinct manner the development of medullary cells from cartilage-cells.

(To be continued.)

MARTINDALE ON JABORANDI AS A POTENT SUDORIFIC AND SIALAGOGUE.

Mr. William Martindale, F.C.S. (*Pharmaceutical Journal*, January 16), writes: Having received, through Messrs. Hearon, Squire, and Francis, a further supply of this remarkable drug, which has excited much attention physiologically and therapeutically in Paris during the last twelve months, information respecting its previously doubtful botanical origin is now obtainable. In my former communication on jaborandi,* I said that I thought the statement of Professor Baillon that it was the leaf of *Pilocarpus pennatifolius* was erroneous, giving as my reason that, having obtained some of the fresh leaves of *P. pennatifolius* from Kew Gardens, these differed so much in taste, odour, and more especially in physiological action from those of jaborandi, that 'Dr. Ringer and others, as well as myself, who watched the cases,' in which both were used, 'and examined the leaves and infusions of both, were satisfied this was not the same as the jaborandi we had tried before.' I further stated that of course as these leaves of *P. pennatifolius* 'were from a plant of hot-house growth, grown in its natural habitat its effects might be different.' I noticed lately that Professor Baillon still adheres to his statement.† Now that we have the whole leaf of jaborandi to compare with herbarium specimens of *P. pennatifolius*, they undoubtedly greatly resemble each other. Still, in our comparison with a specimen of *P. pennatifolius* at Kew, collected near Assumption in Paraguay, Professor Oliver and Mr. Holmes noticed a difference in certain characters; and as jaborandi comes from Pernambuco, near to the Equator, whereas the Kew specimen was collected nearly 1,000 miles further south, beyond the tropic which seems to be its general habitat, there is a great probability that they are not the same; if not the same, jaborandi is a nearly allied, perhaps, as yet, undescribed species. This I leave for Mr. Holmes, who has taken the subject in hand, and will give a full botanical description of the parts of the plant that have been received, and other botanists, to decide.

In forwarding the supply, the agents in Pernambuco wrote that 'it is a medical shrub known by us, but little used, notwithstanding its excellent virtues, as the medical men here prefer using foreign medicines. It is an excellent sudorific in the dose of one

* *Pharmaceutical Journal*, 1874, p. 365.

† *Journal de Pharmacie et de Chimie*, Janvier, 1875, p. 23.

octave to a cup of infusion. It is a good sialogogue. The tincture is used as a friction on paralysed members.*

Of the importation lately received, the leaflets form about one-fourth of its weight, the remainder being stems and leafstalks, with a few roots and fruit, but unfortunately no flowers. Compared with that which I first obtained from Paris, the leaflet of this is much more pungent in taste, and, I believe, for reasons given below, much more active physiologically. When chewed, the taste is piquant, and excites a glowing heat on the tongue, like that caused by pellitory root. I also find, from working with it, that it irritates the skin when applied externally. On the inner surface of the bark of the root, white shining crystals are distinctly visible; but, as Dr Attfield is about to make a chemical investigation of the different parts, it is premature to offer any opinion about these. Therapeutically, Dr. Ringer is continuing his investigations at University College Hospital.

Having heard doubts expressed about the activity of the jaborandi last received, as compared with the results obtained in the first trials I witnessed at University College Hospital, I became somewhat sceptical about its efficacy, and, therefore, expecting to get little results, tried it upon myself. To me, the effect seemed simply marvellous. I made an infusion of sixty grains of the bruised leaf in five ounces of boiling water, let it stand fifteen minutes, and strained it. On pouring the water upon the drug, I noticed that the characteristic odour almost entirely disappeared. The infusion was of a pale sherry colour, had a mawkish bitter taste, but did not excite the glowing heat upon the tongue that the leaf itself did; this I thought strange, and on tasting the dregs I found they still retained their pungent taste when chewed. It was evident to me that, if its diaphoretic properties depended on the principle having this pungent taste, boiling water does not extract it. At 11:30 P.M., on retiring to rest, I swallowed as much of the dregs as I could, probably fifty out of the sixty grains used, and washed them down with the infusion. In five minutes I felt a glow, an increased circulation, an uneasiness in the head, became restless, and the secretion of saliva began to increase. At 11:45, a quarter of an hour after taking the dose, I was perspiring freely. The salivation and perspiration continued to be profuse, until my sight became blurred. At a distance of four feet I could see my wife, but could not distinguish her eyes. On this occurring I became a little anxious, as I had evidently taken an overdose. I requested that Dr. Ringer might be sent for; he came about 12:15 A.M. The impaired vision still continued, but I was glad to find that it was only at a distance—near objects I could see distinctly enough. The pupils of the eyes were slightly dilated, I was informed. The pulse when first noted was 96, and got up to 104. The temperature was not taken. The depression was never very great, but a little before Dr. Ringer came I began to shiver, more clothes were put on the bed, and some spirit and water given to me. The excessive perspiration still continued from all parts of the body. A Turkish bath, which I have frequently had, and seen others have, was nothing to it; the saliva for a time required almost constant ejection; the secretion of this from the glands in the cheeks caused a kind of collapsed feeling in them. My speech was so affected that articulation was both difficult and indistinct. Eventually, about 1 A.M., I was sick, and vomited at first a quantity of saliva

which I had swallowed. By putting my finger in my mouth vomiting was further excited, until a portion of the jaborandi returned. The effects were now subsiding: more spirit and water were given to me, and my night-shirt, soaked with perspiration, was changed. I was put into a warm blanket, and about 1.40 A.M. I fell asleep and slept a quiet sleep till 6 A.M. The pulse on awakening was 88—normally with me it is 80. I got up about 7.30 A.M., and although I felt squeamish all next day, I was able to attend to business as usual. When the action was at its height, on uncovering my arm, I am informed the perspiration passed off in steam from my hand and night-shirt sleeve. The saliva collected, which was distinctly alkaline, measured sixteen ounces; in addition to which, a quantity had flowed on to the pillow while I slept, as it was quite wet in the morning. I came to the conclusion that I should not like to pass through the ordeal again. My thanks are due to Dr. Ringer, whose presence and kindness greatly relieved my anxiety.

We have undoubtedly in jaborandi a drug which produces a marked physiological action; how far it will prove useful therapeutically in cases of fever, diabetes, and other diseases, remains to be seen. A drachm-dose of the last received is no doubt excessive, that is if the whole be swallowed. The strained infusion, from what I hear, produces but little effect.

M. Robin* gives an account of the results of his researches in M. Gubler's wards in Paris, but no mention is made of its peculiar action upon the vision, which, so far as I am aware, has not been previously noted.

A YEAR'S EXPERIENCE IN ST. BARTHOLOMEW'S HOSPITAL.†

The present report has been very carefully compiled by the medical registrar, Dr. Hollis, and the surgical registrars, Messrs. Butlin and Milner; and from its complete and concise character is worthy of even more extended notice than can be given in these pages. St. Bartholomew's Hospital possesses 676 beds; 230 for medical cases, 428 for surgical, while 18 are unassigned; 21 are allotted to diseases of women, and 26 to ophthalmic cases. During the year 1873 there were under treatment 5,902 cases (2,382 being medical and 3,520 surgical). Of this number, 4,530 were discharged cured and relieved, 320 were unrelieved, 563 remained in the hospital at the beginning of 1874, and 489 died; the percentage mortality on the total number under treatment thus being 8.3 (the mortality among the medical cases being 14.6, surgical nearly 4). Fourteen patients were brought in dead, and 395 *post mortem* examinations were held. It will thus be seen that in no fewer than 108 cases, or more than one-fifth of the whole number of deaths, there was no necropsy; a fact in itself which shows how great is the unwillingness among friends of patients to allow such examinations to be held.

The main portion of both the medical and the surgical report consists essentially of two tables; one, in which all the cases of disease are tabulated with regard to their results, and the other in which the comparative frequency and mortality at different

* LONDON MEDICAL RECORD, December 16, p. 794, from the *Bulletin Général de Thérapeutique*, November 30, 1874.

† Statistical Tables of the Patients under Treatment in the Wards of St. Bartholomew's Hospital during 1873.

ages in every class of disease are recorded. This latter table is, the present writer believes, peculiar to St. Bartholomew's Reports, and is certainly one of no little value to the statistician. Following Table I is an appendix, in which brief mention is made of the more interesting examples of disease. It is impossible here to attempt anything like a complete analysis of these statistics, but a few facts may be quoted sufficient to show the nature and extent of the reports. Out of a total of 199 cases of acute rheumatism, ninety-nine were uncomplicated, forty-seven had pericarditis (in three associated with endocarditis), fifty-four had endocarditis, while nine had lung-complications; there were only five fatal cases, two of which were complicated with cardiac lesions and three with pulmonary. There were also 142 cases of subacute* rheumatism under treatment. Of enteric fever there were eighty cases, of which number thirteen (or 16.4 per cent.) died, one of the fatal cases being contracted in the hospital, and one case dying from intestinal hæmorrhage. One case of cretinism occurred, in which there was absence of both thyroid and thymus. There were twenty-one cases of right hemiplegia and seventeen of left, the males being nearly three times as numerous as the females; in one case only is it noted that aphasia occurred with right hemiplegia. A case of locomotor ataxy presented symptoms of lead-poisoning. Among thirty-six cases of chorea, one of which was fatal, seven had heart-disease. Three cases of pericarditis, apart from acute rheumatism, are recorded; one was complicated with left hydrothorax, one with gout, and one with old rheumatic endocarditis. Of valvular disease of the heart there were in all 112 cases, twenty-four being cases of aortic affection (seven with mitral disease), thirty-seven of mitral, and fifty-one are unspecified. In one case of mitral disease there was old thrombosis of the inferior cava, and a varicose condition of the epigastric veins. Pulmonary affections of course form a very large contingent. There were 139 cases of phthisis, fifty-five of which were fatal; there were seventeen of acute and 102 of chronic bronchitis, twenty-three being fatal; fifty-eight of pneumonia; twenty-two of pleuro-pneumonia; and twenty-nine of pleurisy, fourteen being on the right side, thirteen on the left, while two were double. A fatal case of empyæma in a man was due to the rupture of a hydatid cyst into the right pleura. Six cases of typhlitis were treated; one proved fatal from pyæmia. A case of acute hepatitis, following obstruction of the bile-duct, was discharged cured. In a case of leucæmia, transfusion of blood was performed, but the patient was eventually discharged unrelieved. Acute albuminuria furnished twenty-three cases and seven deaths, chronic albuminuria eighty-six cases, with twenty-nine deaths. There were no fewer than seven cases of progressive muscular atrophy, of which six were males, three of these being between the ages of thirty-five and forty-five. The medical report concludes with an elaborate table showing the average stay in hospital of the medical cases; this being 34.26 days. It is further calculated that out of the total number of 230 beds there was, throughout the year, a nightly average of 22.12 beds unoccupied.

Turning now to the surgical report, it may be

noted that the average stay in the hospital of surgical cases is nearly the same as that of the medical, namely, 33.09 days. The appendix to Table I. is planned on a more extensive scale than in the medical section, and from it a few out of the numerous interesting facts recorded may be gleaned. Under the head of pyæmia it is stated that 'a man, aged thirty-one, had a wart removed from his hand by a quack, who then applied burning sulphur to the wound. Within a few days lymphangitis of the arm and glandular abscess, followed quickly by symptoms of septicæmia, pleuritic effusion, jaundice, abscess in neck, etc., from which he, with great peril, recovered.' In a case of tetanus, the symptoms supervened on the cicatrization of a wound in the ham, the nerve not being involved in the injury; the symptoms, at first local, soon became general, and death occurred on the fifteenth day after admission. Three cases of popliteal aneurism were treated by ligature of the femoral artery; one recovered without accident; the second, after gangrene of several toes, attributed to the patient having moved across the ward too early; while the third case died after an ineffectual attempt to control recurrent pulsation by the employment of a second ligature. Two cases of spina bifida were treated, both with fatal result; in one case (an infant six weeks old) injection of iodine was practised, and death occurred in seventeen days from spinal meningitis and pleuropneumonia; in the other case (a male aged five) tapping afforded relief from symptoms of compression for a few hours, when convulsions recurred, terminating in death. Details are given of several cases of fracture of the skull, of which, perhaps, the most remarkable was the following. 'A compound fracture of the frontal bone in a man, aged eighteen, in July, 1871, was followed by a slight necrosis of a portion of the bone. On account of fits, etc., following a second fall, he was re-admitted in December, 1872. Symptoms of compression gradually supervened in March, 1873, and he was trephined when apparently at the point of death. The dura mater was found distended, and the brain distended beneath it. A bistoury was plunged into the brain, and pus spouted out. He recovered well, and in August was able to return to his work.' Remarks are also made upon cases of special interest in injuries to organs and limbs. In the table of surgical operations performed during the year it is recorded that seven primary amputations through the arm, forearm, and thigh, were all successful; one secondary amputation of the leg recovered, while out of thirty amputations for disease through the forearm, hip-joint, thigh, knee, ankle and leg, one only (through the leg) was fatal. Nineteen operations for inguinal hernia were performed (two without opening of the sac); there were seven deaths, in all of which cases the sac was opened. For femoral hernia there were nine operations, six with opening of the sac, four of which were fatal, as also were two of them in which the sac was not opened. Death occurred in all cases save two from peritonitis; in one case it was due to septicæmia, in the other to phthisis, six weeks after operation. Out of a total of 140 cases of erysipelas, phlegmonous inflammation and cellulitis, thirty-one arose in the hospital, and of this number eleven followed operations; there were in all eight deaths from these causes, six of these being cases which were admitted into the hospital with the disease. The surgical report concludes with a table of amputations with the percentage of deaths from 1864 to 1873 inclusive.

* It would be interesting to know what standard is here adopted for the term 'subacute.' The distinction between 'acute' and 'subacute' rheumatism is, in many cases, very difficult to draw.

This table derives especial value from the large number of cases which it includes, and it would be well if, from time to time, the statistics of different classes of disease treated in our hospitals could be thus summarised. It may be remarked that with a total number of thirty-eight primary amputations of the leg the percentage mortality was 52; with thirteen of the thigh it was 30; while in secondary operations these proportions are reversed: thirty-one cases of amputations of the thigh yielding a death-rate of 47·61 per cent., and twenty of the leg, yielding 42·85 per cent. In amputation for disease the mortality after operation on the leg was 30·88 per cent. (eighty-nine cases), while that after amputation of the thigh was 28·34 per cent. (with 163 cases).

Sufficient has been quoted to show how complete these reports are. There can be no question as to the great value of the publication of such annual records of the work done in the London hospitals. It would, perhaps, add to their value, as it certainly would to their utility, if some uniform plan could be adopted, on which all such reports should be drawn up. At present the statistics of each hospital are drawn up on a plan peculiar to itself, so that it is to be feared that much needless labour will be given to the statistic of the future in his desire to collect materials of the natural history of disease.

SIDNEY COUPLAND, M.D.

ZIEGLER ON THE EXPERIMENTAL PRODUCTION OF GIANT-CELLS FROM COLOURLESS BLOOD-CORPUSCLES.

Ernest Ziegler (*Centralblatt für die Medicinischen Wissenschaften*, nos. 51 and 58, 1874,) cut from mirror-glass small glass plates of different sizes, partly quadratic, partly long rectangular, ground off the edges carefully, and affixed to each with porcelain glue a fine cover-glass of the same size, so that there remained between the glass lamellæ an empty capillary space, accessible from all sides, with the exception of the corners. These plates were brought under the skin and periosteum of dogs and rabbits, or were introduced into one or other of the large cavities of the body. This was done under the impression that the colourless blood-corpuscles would penetrate into all the spaces, would wander under the cover-glass and there, independently of the organism, be nourished by lymphatic fluid, and undergo this or that metamorphosis. The author met with many failures, and recommends the following method. Small plates of glass must be used, 10 to 20 millimètres (0·04 to 0·08 inch) long and 10 millimètres (0·4 inch) broad. Large ones easily occasion profuse suppuration. The plates were generally left from ten to twenty-five days in the spot operated on. The best field for operating is the inner side of the thigh of not too old dogs. Rabbits gave no satisfactory results. After the plates were removed they were slightly washed, and at once placed in a 1 per cent. solution of perosmic acid, and allowed to remain there for two days. They were then placed in spirit with glycerine, then in pure glycerine.

The following were the results of sixty-five experiments. An in-wandering of colourless blood-corpuscles took place in all cases. The changes of the same in the first ten days varied according to the direction of the development. After several days, a flattening of the corpuscles and the formation of a cellular mosaic were often to be observed. After this

time the author found the following, up to the twenty-fifth day.

In the greater number of cases only retrogressive changes were observed. The progressive processes showed the different developmental directions.

1. *The Formation of a Reticular Tissue with Enclosed Epithelioid Cells and Rich Development of Giant-Cells.*—This is, without doubt, the most interesting result. The giant-cells consist of finely granular protoplasm and certain numerous large oval nuclei and distinct nucleoli, sometimes with round sharp contours, at others provided with processes. They lie in the above-mentioned reticular tissue, surrounded by cells which in their immediate neighbourhood are of considerable size, but diminish towards the periphery. The size of the giant-cells is very various, and it can be seen, in one and the same microscopical preparation, how they are developed from the colourless blood-corpuscles by increase of the protoplasm and simultaneous increase of the nucleus, till they reach the dimensions of the largest known giant-cells. In preparations in which giant-cells were present, the author never observed the development of blood-vessels.

2. *Development of Connective Tissue and Vessels.*—Similar appearances to those of developing connective tissue were found. The preparations incline the author to lean to the paracellular origin of the reticular tissue. As the first stage in the development of the vessels there is clearly observed a network of peculiarly changed colourless blood-corpuscles ranged one on another, which increase considerably on the surface, and are firmly fixed on the edges, and gradually assume an epithelioid character. In addition to this so-called secondary formation of vessels, the author observed at a later date budlike formations from the wall of existing vessels. Still even here the author thinks that these bud-like formations are formed by the opposition of neighbouring lymph-corpuscles. The author draws the following conclusions.

1. Real giant-cells can develop from colourless corpuscles.

2. Under similar conditions, cytogenous connective tissue with epithelioid cells is formed.

3. These formations are to be regarded as analogous to certain forms of tubercle; or, in other words, tubercle with its giant-cells is an inflammation-focus in which the colourless corpuscles heaped up at any spot (probably intracanalicular—Rindfleisch, Schüppel), undergo a development. This, according to the author, is caused by imperfect nutrition of the cells, in so far as this is not sufficient to form new connective-tissue. According to this view, giant-cells are to be regarded as imperfect new cell-formations.

4. The formation of intercellular substance in reticular tissue is paracellular, arising anew by a cutting off from the sides of the cells.

W. STIRLING, D.Sc., M.B., Edinburgh.

ANATOMY AND PHYSIOLOGY.

TARKANOFF ON THE FUNCTION OF THE SPLEEN. At the meeting of the Paris Society of Biology, on December 26, M. Tarkanoff communicated the result of a series of experiments undertaken to determine the function of the spleen, and to ascertain if it may be considered as helping in the formation of white corpuscles. This opinion has gained so

strong a footing in physiology, that it has become an axiom since the labours of Vierordt and Funk, who, comparing the blood of the splenic artery with that of the vein, established that in the latter there was one white to every seventy red corpuscles. In the arterial blood, on the contrary, the proportion was normal. They thence concluded that the spleen was an organ forming white corpuscles, but they made their experiments upon dead animals. M. Tarkanoff, however, made his experiments on living animals; he performed section of the splenic nerves, when hyperæmia and swelling of the spleen ensued, and at the same time a veritable leucocythæmia. This experiment appeared to him to be in accordance with M. Vierordt's conclusions, since greater activity in the circulation of the liver brought on an increased production of white corpuscles; but at a subsequent period M. Tarkanoff found that a simple wound, without any section of the splenic nerves, would bring on a similar leucocythæmia; the excess of circulatory activity could not therefore any longer be taken into consideration. He therefore wished to investigate the exactness of Vierordt's and Funk's data, and made an exact reckoning of the white corpuscles of the splenic vein and artery on the living animal by M. Malassez's method; but he first felt it necessary to discover in what proportions these corpuscles were present in the arterial and venous systems. The results were so different that he could not arrive at any conclusion, but he invariably found that the white corpuscles were more numerous in the left than in the right side of the heart; and in one analysis alone he found that the left ventricle contained 2,765 corpuscles, whilst the right contained only 1,530. He also established a similar fact in the vessels of the spleen, which is in opposition to what writers have hitherto maintained. The proportion of white corpuscles is always more considerable in the arteries than in the veins; in one case he found 8,900 in the artery, and only 9,500 in the vein. He also ascertained that this increase of the corpuscles in the artery was larger in proportion as the circulation of the spleen became more active. After dividing the splenic nerves he counted 10,000 white corpuscles in the artery, and only 4,300 in the vein. M. Tarkanoff, therefore, concludes that in all instances the white corpuscles are less numerous in the splenic vein, and that this diminution becomes so much the more marked as the activity of the circulation is greater.

ETZINGER ON THE DIGESTIBILITY OF GELATINE-YIELDING TISSUES.—J. Etzinger (*Zeitschrift für Biologie*, 1874, Band x., abstract in *Centralblatt für die Medicin. Wissenschaften*, no. 45, 1874) tested on the one hand the action of artificial gastric juice on the ligamentum nuchæ, tendon, cartilage and bone; and on the other hand fed a dog, whose excretion of nitrogen was diminished to a constant low value by being allowed to hunger for several days, with the proper substances.

The increase in the quantity of nitrogen after the supply of the above substances is taken as the standard for their utilisation in the body.

1. *Bones*.—Bone-powder, prepared by rasping the compact substance of ox-bones, dissolved tolerably richly in hydrochloric acid (0.3 per cent.). After ten days' digestion of 10 grammes (150 grains) of the powder, with in all 1,200 cubic centimètres (rather more than 40 ounces) of dilute acid, only 1.83 grammes remained undissolved. The residue

was richer in organic substance than the original substance, organic substance, however, being plentiful in the solution. The dog experimented on showed, after taking 150 grammes of bone, an increase in the excretion of urea of about 8 grammes *per diem*. An absorption of lime from the bones could not be proved; on the contrary, the quantity of this mineral in the urine showed a diminution. The author supposes that the cause of this phenomenon lay in the diminished decomposition of the tissues of the body through the supply of gelatine. The phosphoric acid showed a small increase. Corresponding to this, the fæces evacuated during feeding with bones contained 308.5 grammes of ash, *i.e.*, somewhat more than the supplied bones.

2. *Cartilage*.—Costal cartilage of a calf dissolved in not inconsiderable quantity in a 0.3 per cent. solution of hydrochloric acid (*e.g.* 24.3 per cent.); but much more on the addition of pepsin (74.9 per cent.). After feeding with cartilage, the fæces only contained traces thereof; the excretion of urea showed an increase of about 11 grammes after feeding with 72.2 of dry cartilage at 100° Cent.

3. *Tendons* were affected little by the action of a 0.3 per cent. solution of hydrochloric acid. After eight days' digestion the amount dissolved in the pepsin mixture was 12.05 per cent.; on the contrary, after three days they were broken up and dissolved, and 94 per cent. had gone into solution. The solution did not form a jelly after neutralisation and evaporation. The ligamentum nuchæ of an ox conducted itself similarly; on digestion for ten days it disappeared completely, only an unimportant residue remaining. The dog, after hungering for several days, received in one day 367.1 grammes of tendon, on the next 360.3 grammes, corresponding to 245.8 grammes of the dried substance. In the fæces only a very minute quantity of tendon could be found. The excretion of nitrogen in the urine rose to 21.2 grammes (the tendon contained 46.4 grammes).

All gelatine-yielding tissues are therefore capable of digestion and utilisation; most extensively tendon, then cartilage, and lastly bone, of which less organic substance is absorbed, probably on account of its rapid passage through the intestinal canal. The author confirms the results of Frerichs and Kühne that gelatine, by digestion with pepsin and hydrochloric acid, loses its property of gelatinising.

SERTOLI ON THE TERMINATIONS OF THE GUSTATORY NERVE.—E. Sertoli (*Gazetta Medico-Veterinaria*, Anno iv., abstract in *Centralblatt für die Medicin. Wissenschaften*, no. 55, 1874) investigated the papilla foliata of the tongue of the horse. For the investigation, the author employed a very interesting modification of the gold method. Small pieces of fresh tissue were placed in a relatively large quantity of gold solution ($\frac{1}{4}$ to $\frac{1}{3}$ per cent.) and allowed to remain therein for eighteen or twenty-four hours, then washed out with water, and placed for twenty-four to forty-eight hours in a 2 per cent. solution of bichromate of potash. They were then washed out with water and placed in absolute alcohol, in which they were completely hardened, and in which the colouring already begun in the bichromate of potash became perfect. The colouring can be accelerated by exposing the preparation in bichromate of potash to a temperature of 30° Cent. (86° Fahr.). The papilla foliata is very richly supplied with nerves. In the subepithelial connective tissue

the nerves form a very dense network, to end in the two following ways : (1) in the gustatory bulbs, which are present in extraordinarily large numbers in the folds and furrows of the papilla foliata; (2) in an intra-epithelial network of fine non-medullated nerve-fibres, intensely coloured by chloride of gold. In addition to this network, stellate bodies coloured dark violet by chloride of gold lie among the pavement-epithelium, the bodies being similar to those described by Langerhans from the human epidermis. Sertoli is inclined to regard them as non-nervous. As this intraepithelial nervous network lies deeply imbedded and protected in the furrows of the papilla foliata, it cannot, according to Sertoli, be regarded as an anatomical substratum of tactile sensibility, and he also claims it as a gustatory organ, as the form of termination of the specific sensory nerves of the tongue. In fact, this same intraepithelial nerve-ending, which often penetrates to the most superficial layers of the epithelium, occurs quite commonly in the papillæ fungiformes of the horse's tongue. These papillæ are distributed in great numbers and with great regularity over the whole dorsum of the tongue, and it is very tempting to regard this form of ending as the anatomical condition of the gustatory sense distributed over the whole surface of the tongue.

The conclusion of the paper is occupied with the consideration of the minute anatomy of the gustatory discs (which are tinged of a very characteristic dark colour by chloride of gold).

PLÓSZ AND GYÖRGYAI ON COAGULATION OF BLOOD IN THE LIVING ANIMAL.—Plósz and Györgyai (*Archiv für exper. Path. und Pharmac.*, Band ii. 1874) confirm the assertion of Naunyn, that injection of lake-coloured blood into the veins of a rabbit is followed in most cases by death, through thrombosis of the right heart and pulmonary artery. Of fourteen rabbits, only two survived the injection. In every case where the animal died, thrombosis was proved to be the cause of death. Outside the body, the addition of lake-coloured blood to normal blood greatly accelerates coagulation.

The second part of the paper is occupied with the question of the injection of foreign blood. Fourteen rabbits received varying quantities of defibrinated blood from hens and turkeys; only one of these survived, two were killed intentionally, eleven died in consequence of the injection, some of these on the sixth day after the injection. As to the cause of death, in three cases extensive thromboses in the right heart, in the large veins of the right heart, and in the pulmonary artery, were found; in five cases the section was not made early enough to determine whether the thrombosis took place *intra vitam* or not; in three cases the presence of thrombi was distinctly ascertained, so that to the blood as such a poisonous action is to be ascribed. [*Vide* the experiments of Creite, who asserted the poisonous action of the serum of the blood of the bird in the rabbit.] The blood-corpuscles of the bird could be discovered several hours after the injection, but they gradually broke down, while the stroma became discoloured, and the nuclei were set free. [*Vide* the results of the experiments of Landois, LONDON MEDICAL RECORD, November 16, 1874, p. 729.—*Rep.*] Blood-colouring matter appeared in the urine. In the frog, the solution of the foreign blood-corpuscles occurs much more quickly than in the rabbit. [*See* also the results of W. Müller's experiments, where no thrombosis was observed after the injection into the veins of dogs of

very large quantities of defibrinated dogs' blood. LONDON MEDICAL RECORD, June 24, 1874, p. 388.—*Rep.*]

DANILEWSKY ON THE RESPIRATION OF MUSCLE.—B. Danilewsky (*Centralblatt für die Medicin. Wissenschaften*, no. 46, 1874) has investigated this subject in Sczelkow's laboratory. It is a well-established fact, that muscular activity causes an increased consumption of oxygen in the muscles. As to the significance of this fact, physiologists differ in their opinions (Hermann and Ranke.) The absorption of oxygen, as well as the excretion of carbonic acid, both of the active and passive muscles (gastrocnemii of a frog), at different temperatures, were carefully measured by means of a special apparatus devised for this purpose. The muscles were weighted with one gramme. From a table of the gas-analyses, which were conducted after the method of Bunsen, he arrived at the following results.

1. The quantity of carbonic acid excreted by a tetanised muscle, in comparison with that by a passively moved one, is smaller, the higher the temperature.

2. The absorption of oxygen by the active muscle always remains behind that of the passively moved one. It may, therefore, be concluded that this does not stand in direct connection with the process of muscular contraction. This is explained by the unequally greater contact of the passively moved muscle with new air than in the tetanised one. The increased absorption of oxygen by the passively moved muscle produces almost no corresponding increase in the excretion of carbonic acid. One must, therefore, assume that both factors in the respiration are, within certain limits, independent of each other; that muscle can take up a very large supply of oxygen and conceal it for a long time in its plasma without excreting it in the form of carbonic acid. The absorption of oxygen increases in active muscle with the temperature.

GOLDZIEHER ON IMPLANTATIONS IN THE ANTERIOR CHAMBER OF THE EYE.—W. Goldzieher (*Archiv für Experiment. Pathol. und Pharmac.*, 1874, Band xi., abstract in *Centralblatt für die Med. Wissenschaften*, no. 52) has adopted a method similar to that of Zielenko, who placed in the lymph-sacs of frogs different tissues, and observed the changes they underwent. The author used the anterior chamber of the eye of rabbits, and placed in it conjunctiva, nasal mucous membrane, nerves, cornea, etc.; the advantage being that the coarser changes could be continually observed and controlled through the cornea, which almost always remained transparent. He found that the bodies introduced very soon became attached and vascular, either by the iris or by the conjunctiva, by means of the cicatrix in the limbus corneæ. They became either encapsuled, the iris encircling them like folds, whereby cysts might be formed (so called epidermoid iris-cysts), or they increased by sticking to some structure in the interior of the eye, and either shrivelled or developed further, either in all parts, or only in one (epithelium of the nasal mucous membrane). The proliferating epithelial cells did not behave in the foreign tissues as irregularly developing tissues, which destroyed the texture of adjoining parts, but conducted themselves after their physiological type.

FELTZ AND RITTER ON THE INFLUENCE OF THE INJECTION OF BILE ON THE ORGANISM.—V. Feltz and E. Ritter (*Comptes Rendus*, lxxviii. 1874), injected fresh bile into the veins, and observed the following phenomena. 1. Tetaniform convulsions occurred, which were followed by coma, insensibility and death from a large dose. 2. There were slight decrease of the pulse, and diminution of the bodily temperature by 1° or 2° Cent. 3. There were pronounced salivation, vomiting of biliary masses, and bilious, sometimes bloody diarrhœa. 4. The blood showed fat-granules, increase of fat, and cholesterin. The blood-corpuscles showed a tendency to flow together. The quantity of oxygen was diminished, and that of carbonic acid increased. On shaking with oxygen, the blood did not absorb so much of it as normal blood. 5. The quantity of urine was increased, and only with very large doses of bile did it contain albumen and bile-pigment; on the contrary, it contained regularly a substance which had many resemblances to indican. Only when the animal died rapidly, was the urine blood-coloured from dissolved blood-colouring matter.

PURVES ON THE PLACE WHERE THE WHITE BLOOD-CORPUSCLES WANDER OUT OF THE VESSELS. L. Purves (*Onderzoekingen gedaan in het Physiol. Labor., Utrecht*, 1873, iii.) to investigate the place where the white blood-corpuscles pass through the wall of the vessel in Cohnheim's experiment on inflammation, injected a solution of silver into the vessels of a frog prepared after the manner of Cohnheim. The colourless corpuscles, without exception, wander out between the boundaries of the epithelioid cells. They never pass through the substance or through the nucleus of an epithelioid cell. According to the author, the red-corpuscles only pass out by those channels which have been previously made for them by the colourless corpuscles. The author found no stomata of any kind on the epithelium of the vessels.

WM. STIRLING, D.Sc., M.B.

GOLDING BIRD ON IMBEDDING IN ELDER-PITH FOR CUTTING SECTIONS.—C. H. Golding Bird (*Quarterly Journal of Microscopic Science*, January, 1875) finds elder-pith, much used in former years, a very favourable imbedding material for cutting sections. The principle recommended by the author is the same as that adopted by Ranvier, viz., the swelling of the parenchymatous tissue of the dried pith in the presence of moisture. The object to be cut is placed in elder pith, and this is fitted into Ranvier's microtome. If water be poured upon it, the pith will have swollen in a very short time sufficiently to hold the specimen firmly in its place. 'As to the quality of the sections obtained, I am almost converted,' says the author, 'to the belief that it matters but little, except in one or two cases, how or in what one imbeds, but that a good result is rather owing to the skill and ingenuity of the manipulator in each particular case. Every one upholds, naturally, the way in which he himself is accustomed to work, and rightly so.'

MEDICINE.

JULIUSBURGER ON GASTRO-PULMONARY FISTULA FROM A PERFORATING ULCER OF THE STOMACH.—Dr. P. Juliusburger, of Breslau, narrates this case in no. 51 of the *Berliner Klinische Wochenschrift* (December 21, 1874). The patient, aged forty-three, was a confectioner, and steward of a friendly society. His father and brother died with symptoms of phthisis. For more than a year he had been treated for dyspepsia; he had suffered for some months from bronchial catarrh; and during last winter he had several losses of blood *per anum*, in consequence of which he was very anæmic. Anorexia, weight and fulness at the epigastrium, particularly after meals, eructations, severe cardialgia, irregular defecation, colic and flatulence were the principal gastric symptoms. No vomiting had been noted. He took little medicine, from an idea that the bleedings were salutary! but he adhered pretty strictly to the diet prescribed. From his appearance, family history, and chronic dyspepsia, tuberculosis was suspected. There was, however, no percussion-dulness over either lung, but under the right clavicle expiration was harsh and prolonged, whilst above it there were cooing and whistling râles. The second sound of the pulmonary artery was intensified. Change of air was prescribed, but ere he left a catastrophe occurred on June 9, which led to his death on September 7. Unknown to his medical attendant, he had for some days been taking Ems water (from the Krähnen spring) with whey. Hæmatemesis had also been going on for some days. On June 9, during defecation, he was suddenly taken with violent pain in the stomach, and symptoms of abdominal collapse. The pain proceeded from the ileo-cæcal region, extended all over the right half of the abdomen, and upwards over the epigastrium and liver to the right shoulder. The epigastric and right hypochondriac regions were distended, forming an elongated tumour which overlapped his thorax; the swelling, in a less marked form, extended to the ileo-cæcal region. He was ordered one-sixth of a grain of morphia every hour; ice externally, and ice to suck. Next day there was some reaction. The swelling in the gastro-hepatic region had increased, while just above the navel there was a fork-like furrow, reaching across the abdomen, below which the lower belly was distended, though not so greatly as the upper portion; it was also less tender. The percussion note was tympanic over the whole abdomen, and on the right side as high as the fourth ribs, and thence even to the right axilla; the normal liver-dulness was quite wanting. On the third day the bowels acted spontaneously, his pain was much relieved, and wine, milk, and broth were allowed him. On the fourth day, the rest of the belly being soft and flat, the isolated longitudinal swelling of the

epigastric region became still more visible. Pulse, 96-100; temp., 101.3°; respirations, now costo-abdominal, 28 per minute. Percussion of the right thorax posteriorly gave no abnormal sound, except that the liver-dulness was a mere narrow stripe. He was now allowed to use a sofa for a short time daily. On the twelfth day he lost much blood *per anum*, and was again collapsed. From this he was restored by stimulants; and with three-grain doses of tannin, followed by bark and wine, he improved so much that he was soon allowed to sit out of doors, and gained some colour; his pulse and temperature still kept high, with slight evening exacerbations. This state of things lasted till July 5, when he had a severe rigor, followed by expectoration of vast quantities of fetid, partly fluid, partly purulent, and partly solid matter; the latter in brown masses, mixed with blood. At the same time similar masses passed *per anum*. He was found in bed, sitting up, with full frequent pulse, rather quicker respiration than before; free from pain, but unable to lie down, every attempt to do so being followed by belching of fetid matter, and the expectoration of these masses. Inspection showed the epigastrium much flattened, whilst palpation disclosed a flat resistant tumour, about the width of the hand, which seemed clearly to be the left lobe of the liver. Below the edge of the ribs on the right side there was a narrow strip of dulness, over which the tympanic note again occurred as it had been. Behind, from the liver-dulness to the spine of the scapula upwards, and laterally to the axilla, there was a flattened percussion-note, very weak pectoral fremitus; the breath-sounds were faint, almost inaudible; but near the vertebræ, and in the axilla, bronchial breathing was heard. Elsewhere there were catarrhal sounds. At night this posterior dulness in the right thorax was changed for a tympanic note, and breath-sounds were clearly heard, mingled with moist râles of medium size. His appetite was good. There was no special increase of fever. One-sixth of a grain of morphia procured no sleep, for towards 1 A.M. the expectoration began again. The percussion-note was dull once more over posterior part of the right lung—whilst at night it was again tympanic. These changes went on from day to day, varying as the percussion was performed before, or after the expectoration—which itself was usually preceded by distension of the epigastric region. Sometimes the expectoration followed pressure on the patient's back, either from his lying down, or from the flat hand pressing there. Examination of the sputa showed pus-cells, and masses or plugs of fat, to be the chief constituents; the reaction varied, being acid at one time, alkaline at another. These physical signs led to the conclusion that the stomach and right lung communicated with each other, and the presence of portions of food in the sputa one day confirmed this. The patient some hours previously had supped on farinaceous food, and such quantities of this were expectorated, as forbade belief that it could have merely adhered to the mouth or pharynx. Tonics, whey, and morphia at night were the treatment. For some weeks there was little change. The sputa were coughed up several times a day; similar masses, mixed with blood, passed in great quantity *per anum*. The long epigastric tumour gradually extended into the right hypochondrium, giving a dull percussion-note for about a handbreadth. Blood sometimes appeared in small quantity in the sputa. Fever was slight. The appetite was good, but the patient grew

thinner. Sleep was only obtained by morphia, of which nearly a grain was required every night. The bronchial symptoms at both apices were intensified. In the twelfth week the expectoration ceased. Expectorants did not relieve—he lost appetite, had hectic sweats and high fever at night. Rigors which shook the bed occurred almost daily, indicating pyæmic processes; the apex of the right lung solidified, and finally, at the end of the twelfth week, the almost skeleton-like patient passed away in a comatose condition, with signs of œdema of the lungs.

The *post mortem* examination, fourteen hours afterwards, showed the pylorus adherent to the suspensory ligament of the liver. In the posterior wall of this part of the stomach there was an opening about the size of a sixpence, above which was a cavity as large as a fist, containing air and brownish pus. It extended into the right half of the thorax; was bounded on the right and in front by the thoracic wall, below by the liver, on the left by the stomach, and above and behind by the diaphragm. The latter was fairly adherent to the pleura and right lung, and had an opening almost as big as that in the wall of the stomach. Corresponding to this hole the lung-tissue was destroyed, and allowed the openings of several bronchi to be seen, and these communicated with the right bronchus and trachea. There were disseminated tubercles in both lungs, the right apex was infiltrated with tubercles, and had some small cavities. The liver was moderately enlarged and fatty. The spleen had almost countless pyæmic infarctions disseminated through it. The heart, kidneys, and great vessels showed nothing abnormal. In the stomach there was another ulcer, almost as large as the first, and nearly opposite to it in the pyloric portion, in the cardiac part and fundus, six to ten scars of small ulcers healed up, and two more large fresh ulcers in the greater curvature, looking as if just punched out. No further examination of the body was made for want of light.

Although pathologists may be unwilling to admit this, it seems probable that these ulcers originated in tuberculous disease. How else shall we explain the numerous ulcers? He was no drunkard, took no corrosive substances, and had no disease of the circulatory organs. It seems probable that his inherited diathesis gave rise to the disease in his stomach.

W. BATHURST WOODMAN, M.D.

HAUKE ON THE PNEUMATIC CUIRASS.—Hauke (*Wiener Medizinische Presse*, nos. 34 and 38, 1874, and *Centralblatt für die Medicinischen Wissenschaften*, no. 58, 1874) has invented two kinds of cuirass in order to rarefy the air around the thorax. The one apparatus consists of a convex thin sheet of iron, provided at its edges with caoutchouc tubes filled with air. It is made to encase the thorax, and to leave uncovered only the shoulders and the region corresponding to the vertebral column. The other is made of cane, and is covered with air-tight cloth in the shape of a shirt. If applied to the body, the apparatus encloses the thorax, the neck, the arms, and the upper portion of the abdomen. In the space thus created around the thorax, the air may be rarefied by means of some contrivance, either with each inspiration or permanently. For this last purpose, however, the cane apparatus must be used, because the other would cause pain by the continued pressure. By rarefying the air around the thorax, Hauke intends to equilibrate the retractile force of the lungs, and, if the rarefaction be increased to a certain

degree, to give preponderance to the pressure of the intrapulmonary air. In this way, the lungs may be expanded and movements produced similar to those of inspiration. From these, however, those movements differ in so far as the diaphragm is relaxed, instead of being contracted, and is pushed upwards into the thoracic cavity.

Hitherto Hauke experimented only upon himself. He found that the rarefaction of the air around the thorax of from 1.36—1.24 atmosphere, energetically excites to deep inspirations. If the ordinary atmospheric pressure be re-established, the dilated thorax rapidly returns to its former position. Expiration is thereby facilitated. Respiration carried on in this way gives rise to a sensation of great ease and comfort; but this does not take place if the rarefaction be permanent.

This mode of treatment has not yet been applied in practice. Hauke thinks that the rhythmical application of the apparatus is indicated in cases of insufficient inspiration. It is preferable to the inhalation of compressed air, because it allows the filling of the vessels of the lungs. The cases most suitable are (1) the asphyxia of the new-born; (2) the congenital or acquired atelectasis; (3) the inspiratory dyspnoea of capillary bronchitis; and (4) rickety affections of the thorax, in order to prevent or to cure the deformities due to the collapse of the lung.

The continual rarefaction is said to be indicated in cases of overfilling of the systemic veins, on account of the aspiratory force exerted by the rarefied air upon the blood returning to the heart.

I. B. BERKART, M.D.

PEPPER ON THE LOCAL TREATMENT OF PULMONARY CAVITIES BY INJECTIONS THROUGH THE CHEST-WALLS.—After a full historical account of this treatment, Dr. W. Pepper states (*American Journal of the Medical Sciences*, October, 1874) that, by evacuating the cavity, it considerably lessens cough, and thus favours rest of the diseased lung. It enables us also to disinfect the purulent contents, and to stimulate the walls of the cavity. Dr. Pepper thinks the effects on the walls of the cavity are of the most importance. Iodine and carbolic injections have been used. Dr. Pepper has only employed weak solutions of iodine. He does not make a permanent communication with the cavity, but on each injection introduces a fine cannula. This treatment does not evacuate the cavity; it only modifies the condition of the walls, and lessens or removes the pyogenic membrane. At present, he has only punctured through the first, second, or third interspace, usually in the line of the nipple.

He uses an apparatus like a large hypodermic syringe capable of holding twenty-five minims. He introduces the needle from one and a-half to two inches. He employs dilute compound solution of iodine, at first Miv to Zj , now he uses Mxij to Zj , and of this solution he uses Mxxv for each injection once a week.

He shows that the operation can be performed without pain or any bad consequences, though he disadvises its use when much healthy lung lies between the cavity and the chest-walls.

He has made over seventy punctures in all. Dr. Pepper concludes that, whilst the operation can be performed without risk, it lessens expectoration and quiets cough, and thereby greatly improves

health. He believes that physical examination justifies the conclusion that this treatment causes contraction and cicatrization of the cavity.

SURGERY.

PARONA ON THE TREATMENT OF VARIX BY INJECTION OF HYDRATE OF CHLORAL.—Dr. Parona, in a two years' report on the surgical practice in the hospital at Novara, describes (*Gazzetta Medica Italiana-Lombardia*, December 12, 1874) ten cases of varix of the leg treated by the injection of hydrate of chloral.

Case 1 was that of a man named Giovanni Masseroni, aged seventy, a gardener, who at the age of twenty had varicose veins to such an extent as to exempt him from military service. Ulceration and other complications of varix began when he was forty years old. When he came into hospital, the right saphena vein was only slightly varicose; the left was varicose up to its junction with the femoral vein. There was an ulcer on the leg. After some days of rest, a solution of hydrate of chloral of the strength recommended by Porta (a gramme for each injection) was injected at several points in the course of the vein. The operation was attended and followed for a short time by smarting; coagula were immediately formed; there was no local nor general disturbance; nor were there any symptoms of hypnotism, although several grammes were injected. Three injections were made at other points five days afterwards. The patient left the hospital twenty-two days after his admission in a very satisfactory state; he said that his leg felt lighter and was quite painless. The varices were greatly reduced and indurated.

Case 2. A man named Francesco Petracchi, aged forty-five, had varix of both internal saphena veins. Two injections of hydrate of chloral were made in the left leg and three in the right—three grammes in all being used. There was some threatening of phlebitis in the left leg; this was, however, soon subdued by cold applications and rest, and, at the end of fourteen days, the veins were converted into hardened painless cords. Three months afterwards, the man remained in as satisfactory a state as when he left the hospital.

Case 3. Pietro Fratta, aged forty-eight, was admitted with circumscribed varicosity of the upper and inner third of the right leg; both the internal

saphena vein and its collateral branches were enlarged, and there were two ulcers on the leg. The patient presented all the signs of a high degree of paludal cachexia. Three injections of hydrate of chloral were made into the dilated veins; obliteration took place slowly. The ulcers, however, showed no disposition to heal; their edges became tumid and partially sloughed; erysipelas of the limb, preceded by rigors, set in; and it was not until after repeated doses of quinine and prolonged tonic medication that the patient was able to leave the hospital. The cure remained permanent many months afterwards.

Case 4. Carlo Comello, aged sixty-eight, had varicose veins of the whole right leg, as far down as the inner condyle, with five ulcers, and an eczematous state of the skin. Five injections were made on two occasions. The result was successful, the veins for the most part remaining pervious. Seven months afterwards, he reported that he had been able to follow his daily calling as an agricultural labourer, and to walk long distances without inconvenience. The veins were rather more dilated than when he left the hospital.

Case 5. Battista Chierico, aged eighteen, was admitted with varicose veins of the left leg, accompanied with an ulcer. Three injections of hydrate of chloral were made. There was a little local reaction, which was subdued by cold applications. The patient left the hospital at the end of twenty days, with the veins obliterated and the ulcer cicatrised.

Case 6. Francesca Lommi, aged thirty-five, was admitted with varices and an ulcer of the left leg. The local troubles produced thereby had obliged her to keep her bed from time to time for seven years. After four injections of hydrate of chloral, the varicosities disappeared, and the ulcer healed rapidly. The patient left the hospital, and, when last heard of, was able to stand all day, and to walk long distances without the least inconvenience.

Case 7. Catterina Urietti, aged forty-six, had suffered for some time from varix of the right leg, and had had ulcers for about a year before her admission into hospital. Three injections of hydrate of chloral were made; one into the internal saphena vein just below the knee; another into the anastomosing branch between the external and internal saphena veins at the upper and anterior part of the leg; and the third into a varicose dilatation just above the inner ankle. The first injection at once produced coagulation without any consecutive accident; the second was followed by coagulation, but produced a superficial blackish eschar of the size of a lentil, which was detached in about twenty days without giving rise to any accident; the third did not produce complete coagulation, but only contraction of the venous sac. On repeating the injection at the same point a few days later, complete coagulation followed. The ulcer cicatrised very slowly. Dr. Parona has had this woman under constant observation for nearly a year; her condition remains perfectly satisfactory.

Case 8. Epifanio Torsani, aged sixty-four, was admitted with a large varicose ulcer of the lower third of the right leg. Injection was made into the dilated vein, at three points above the ulcer. The reaction was very slight; coagulation was perfect; and there was no hypnotic action. The ulcer was healed in forty days; and the patient left the hospital without a trace of varix.

Case 9. Pietro Cucchetti, aged fifty-one, had had varix of the right leg from the age of twenty. For some years he had suffered from ulcers, erythema, and swelling of the leg, which occasionally disabled him from work for many months together. The internal saphena vein from the upper part of the thigh to the knee was as large as a little finger; and beneath the knee, on the leg, were two varicose nodules, with large varicose veins between them. Injections were made on two occasions, and were followed by cicatrization. The patient left the hospital, contrary to Dr. Parona's advice, before the treatment was completed; the lower varicose nodule still remaining. Circumscribed phlebitis affected him some time afterwards; but, when last heard of, the veins were in a much less dilated state than before the injections, and the patient was able to work all day in the fields.

Case 10. Giovanni Caccia, aged thirty-five, a country labourer, was admitted with varicose ulcer of the right leg, and varix of the internal saphena and collateral veins. The patient presented all the signs of paludal cachexia. After the oedema of the limb had been subdued and the patient's general condition improved, three injections of hydrate of chloral were made into the most dilated portions of the veins. The operation was followed for some hours by smarting, and for some days the patient had pain and swelling in the course of the veins. Coagulation and induration took place; the pain and swelling disappeared, and the ulcer healed. When, however, the patient was about to leave the hospital, he was suddenly seized with rigors; the leg became painful, erysipelas set in, and the ulcer reopened. The patient's pulse increased to 130, and his temperature to 41° Cent. (105.8° Fahr.); the erysipelas extended to the thigh and the back; the tongue became dry; the patient had profuse sweating; there was swelling of the left wrist and right shoulder; and death followed. There were no indications of thrombosis. At the necropsy, pus was found in the two joints that had been swollen, but there were no visceral abscesses. Suppurative periphlebitis was found in the right leg. In the lumen of the veins, both superficial and intramuscular, were long masses of fibrin dyed with hæmatin; and where the injection had been made, the walls of the veins were contracted and thickened, and the lining membrane was wrinkled and closely adherent to the clots.

Dr. Parona draws the following conclusions from his cases and from those which have been elsewhere published. 1. The treatment of varix by hydrate of chloral has, up to the present time, been sufficiently harmless. 2. In the majority of cases, the result of the operation is permanent and complete closure of the varicose veins, with an insignificant amount of reaction. 3. If a coagulum be not formed, the operation may be repeated in a few days without inconvenience. 4. The operation is very rarely followed by phlebitis, suppuration, ulceration, or the escape of coagula. 5. Sloughing of the skin on the point of puncture occurs rarely, and is not severe; it depends on want of skill or of care on the part of the operator. 6. The operation is rather painful, and the ulcers generally cicatrise rapidly after the veins have become obliterated.

A. HENRY, M.D.

MACKENZIE ON THE TREATMENT OF BRONCHOCELE.—The *Birmingham Medical Review* for January 1875 (no. xiii.), contains an article on this

subject by Dr. Morell Mackenzie, with seventeen life-like illustrations from photographs. This department of practice has, for the most part, been relegated to surgeons, although some forms of the disease more naturally come to a physician on account of the peculiar symptoms they set up, or by which they are accompanied. The candid student of history will hardly accuse British surgeons of any excess of zeal in this matter, since nearly all the operations and new methods of treatment have been American or continental; whilst, with some few exceptions, the various forms of this affection, however distinct in their nature, were all jumbled together in most of our surgical text-books, prior to the publication of Dr. Mackenzie's paper in the *Lancet* (May 4, 1872). It will scarcely be possible much longer so to confound things that differ. For clinical purposes, the following classification of goitre is very convenient:—1. Simple or adenoid; 2. Fibrous; 3. Cystic; 4. Colloid; 5. Vascular. The disease may present the characteristic features of any one of the types referred to, or many of the different varieties may be associated together in varying degrees, and in different situations of the gland. This fact will be readily understood when it is borne in mind that the various kinds of bronchocele are generally different stages of development—sometimes progressive, sometimes retrograde—of the simple hypertrophied gland. Hence there are certain sub-varieties dependent on the combination of two different forms of disease, or on the special arrangement of the elements of a single variety. The principal of these are (a) fibro-cystic, a term which requires no explanation; and (b) fibro-nodular, a modification of the ordinary fibrous bronchocele, in which the fibrous structure has undergone retrograde development of a cirrhotic character. Of 447 cases (366 hospital, 81 private patients) 104 were adenoid, 187 fibrous, 23 colloid, 76 cystic, 26 fibro-cystic, 29 fibro-nodular, and 2 vascular. In the first, or simple form (*struma follicularis mollis* of Virchow) which sometimes disappears spontaneously when sporadic, Dr. Mackenzie does not rely upon iodine alone, although this is commonly regarded as a specific in endemic cases. He says that simple hypertrophy occurring in weak anæmic girls is most effectively treated by iron and hygienic measures; whilst cases not yielding to internal treatment may almost invariably be cured by counter-irritation, or internal and external treatment combined. The liquor epispasticus B. P., applied about twice a week, on alternate sides of the throat, is preferred by him to biniodide of mercury ointment. If the latter be used at all, it should be strong. Want of direct sunlight appears to render it less useful here than in India. Electrolysis is often very useful, a mode of treatment introduced by Dr. Althaus. The ointments of plumbic and potassic iodides are of little use *per se*. The 104 cases show the following results of treatment. Cured by the internal use of iodine solely, twenty-one; in nineteen cases iodine pigment was applied as well, thirteen of these were cured, six relieved. Of eleven treated by pigment alone five were cured, two relieved, four were lost sight of. Of thirteen cases treated by electrolysis nine were cured, in two the goitre was diminished; two which resisted treatment were subsequently cured by subcutaneous injections of iodine. Nine other cases were cured by this latter method of treatment. Fibrous bronchocele may be treated by hypodermic injections of iodine, by setons, or by caustic darts. Dr. Mackenzie has

abandoned all these methods except the last, because it does not require the patient to give up his ordinary occupation for a single day. Out of seventy-three cases thus treated, fifty-nine were cured, nine relieved, two left off attending, and only two were unbenefited. Reference is made to papers by Dr. Wood, Dr. Luton, of Rheims, Lücke, of Berne, Alquié, of Montpellier, Bonchucourt, Schwalbe, Hardy, Stoerk, and Lévêque, on various means and methods of injection. There are some useful hints as to the syringe to be employed. In the cases given above, the tinct. iodi B.P. (one in twenty) was used. Subsequently simple alcohol, or iodine in alcohol of 90 per cent. (one in twelve), and saturated solution of iodide of potassium, as used by Dr. Bertin, have been employed. With very strong solutions only a few drops should be used; other precautions are mentioned in the paper; ether spray should precede. No bad effect has followed this method in either Dr. Mackenzie's practice or that of Luton, Lücke, Schwalbe, Stoerk, or other physicians. Several illustrative cases are appended. Cystic bronchocele is treated by our author with solution of perchloride of iron—the fluid being left some hours in the cyst, sometimes after a preliminary tapping, which should never be complete. Of fifty-nine cases which submitted to treatment fifty-eight were cured, and one died from the entrance of air into a vein. Dr. Mackenzie now uses a syringe devised to prevent the entrance of air. The duration of treatment is from three weeks to four months, six to eight weeks being a usual time. The following are his conclusions (in substance not in words). 1. Cysts as large as a hen's egg should always be actively treated; so should smaller cysts if they cause serious dyspnoea or dysphagia. The best mode of treatment is that which converts the cyst into a chronic abscess; this is best done by ferric perchloride, to guard against hæmorrhage. Iodine injections in this form often cause sloughing. This treatment of cysts is not devoid of risk from profuse suppuration; and in common with all operations in the neck, there is a danger of air entering a vein, and causing sudden death. In pure cystic goitre this risk is, however, very small. Several cases in illustration are appended to this portion of the article.

[The reporter thinks the profession greatly indebted to Dr. Mackenzie, not only for much information on these little studied subjects, but for the candour with which he has recorded his cases, and for the careful attention to detail which they display.—*Rep.*]

BALNEOLOGY.

SALES-GIRONS ON THE NEW WINTER THERMAL ESTABLISHMENT OF DAX.—Dr. Sales-Girons writes as follows (*Thermes de Dax*, no. 5, November 20, 1874).

It was not as a place of luxury that Dax attracted me: for the English, who make the prosperity of winter stations, have not found it out. It was as a city of hot mineral waters that it charmed me. The very pavements are hot, and the atmosphere is charged with the vapour of the abundant sources. I was quite in my element, as a doctor travelling in search of a respiratory diet, when I entered the new and comfortable establishment. It is at once a perfect bath-house and hotel. The basement-story is erected over a spring of 140° , and in it a large gallery 140 yards long gives access to all the baths. In summer fresh air is made to circulate in it, but in winter it is kept, for the benefit of the patients, at a temperature of 64.4° , and it would be easy to make it warmer by opening some of the doors which open on the above-mentioned spring of 140° . On the first floor, a gallery of the same length encloses all the rooms of the visitors. The vestibule, the rooms for play and for reading, the drawing room, the dining hall, all open on the gallery, and a constant temperature of 64.4° is preserved. Including the gallery below, a patient may walk 280 yards without stirring abroad.

The moisture of the air, which can be impregnated at pleasure with the vapours of mineral waters, is graduated in accordance with hygrometers placed at different points. The gases of the sources of Dax, which are particularly rich in azote, accompany these vapours, and can be modified so as to make the air inspired contain more or less oxygen, according to the respiratory wants of the patients.

Here every application of water is to be found. The baths of mineral mud, which first gave Dax its reputation, are admirably applied in rheumatism of the joints. The latest improvements suggested by modern science are to be found here. Baths and douches of all sorts, whether of fluids or of vapours, or of gas, are all administered here at the desired temperature. Even hydrotherapy, which may appear at first sight an anomaly in a thermal establishment, can be carried out by the use of cold water, which has been laid on. Besides all this, arrangements have been made for pulverisations, which are useful in laryngeal and bronchial affections; and the sulphur-waters of Gamarde have been brought a distance of two leagues, for employment in such cases. I could not help picturing to myself, how much might be done for pulmonary patients in an institution so well arranged for winter cures. There is a constant temperature in the interior of from 59° to 68° during the cold season; tepid vapours to diffuse through this atmosphere to moisten it, nitrogen to correct its

sharpness. The locality appeared to me to be predestined for an antiphthisical abode, where all the elements of a respiratory diet have been supplied by nature from its underground workshop.

There is no town or village in France where similar advantages are to be obtained, and at present all these advantages are found combined in one of the finest establishments I have ever inspected. In the mean time Dax is unique; but when it is not able to meet the requirements of all the patients from the north, who are sure to crowd to it, doubtless similar establishments will spring up elsewhere. As a winter *maison de santé*, the Dax establishment is quite a model one in cases of rheumatism, of neuralgia, of bronchial catarrh, and of more serious pulmonary affections, that are looking forward to regular mineral-water treatment next summer.

[This enthusiastic account of Dax comes from Dr. Sales-Girons, well known for his special treatment of various bronchial, laryngeal, and pulmonary affections at Pierrefonds. One who has invented various improvements in the use of the sulphur-waters of that place, must have examined Dax with a critical eye. Dax is undoubtedly well worthy of the attention of those who regard a regulated winter temperature as of primary importance in the treatment of affections of the respiratory organs. There are indeed warm chambers and inhaling rooms at two Pyrenean winter stations, Amélie and Le Vernet. But they are on comparatively quite a small scale, and are not very inviting.]

Dax itself is an uninteresting, dull old town, in a flat country. It has the remains of some Roman walls; and the Romans were attracted to it by the hot water of a temperature of about 140° , which issues in surprising abundance. The winter climate of Dax is a shade warmer than that of Pau, from which place it is distant about two hours by train.

The new establishment supplies a specimen of the sort of thing which Dr. Daubeny and Dr. B. W. Richardson recommended for Bath. Such a plan is perfectly feasible. The waters of that place are, if not so hot or quite so abundant as those of Dax, still sufficiently so. They contain plenty of nitrogen, and in mineral constituents are considerably superior to those of the other place. We hear of a master of the ceremonies being appointed to Bath. Surely its Corporation might take more active measures, and endeavour in a variety of ways to attract patients to those waters, which, although they have never been quite deserted, have been strangely neglected during the greater part of this century. See an excellent account of a French doctor's recent experience of Bath by Dr. Tilt, in the *Lancet* of October 24.—*Tr.*] J. MACPHERSON, M.D.

REVIEWS.

Cholera: How to Prevent and Resist it. Translated from the German of PROFESSOR VON PETTENKOFER, with Introduction, Notes, and a Report on the Cholera Conference of Vienna, by THOMAS WHITESIDE HIME, B.A., M.B., etc., Lecturer on Obstetric Medicine and Diseases of Women, Sheffield. London: Baillière & Co., 1875.

It may fairly be asserted that the science of medicine is being rapidly rescued from the idolatry of theory and vague speculation, and that it, like other branches, is being illuminated by the light of

experimental research. It is a subject for congratulation that so able a physicist as Professor von Pettenkofer has devoted himself to the elucidation of one of the most difficult and important questions which affect the health, and consequently the happiness of men, viz., the etiology and mode of propagation of typhoid fever and cholera. He has been thus engaged for more than twenty years, and the results of his labours are eminently deserving of attention. It is with great pleasure, therefore, that we direct attention to Dr. Hime's valuable work, which supplies a real want. We fully agree with his remark that a vast amount of light would be thrown on such questions if scientific men, though non-medical, would lend their well-trained powers of investigation to solving them. As Dr. Hime observes, 'Investigations as to the mode of propagation, the dependence on telluric and atmospheric influences, the portability, contagiousness, etc., of such diseases as typhoid fever and cholera require no previous medical training The more spies are engaged tracking our enemy the more likely will be his discovery.' Dr. Hime's introduction very lucidly treats questions connecting disease with an impure soil, which, as being frequently the *primum movens*, he regards as more immediately requiring attention even than the air. His statement that there are fifteen acres of ash-pits in Sheffield, in some parts many yards deep, is a striking illustration of the extent of soil-pollution in large towns. He adds force to these observations by a thoroughly scientific elucidation of the movements of the ground-air under and around our houses. He also explains fully the physical conditions which govern the movements of the ground-water, so as to render the apprehension of von Pettenkofer's works more simple.

The most superficial observer must have noticed the apparent capriciousness of the movements of cholera. A town which escaped invasion this year may be ravaged next year, or only a very few cases may occur. Some towns again enjoy almost complete immunity, though subject to frequent importations of the disease, and lying close by towns which suffer greatly and frequently. There must, therefore, be some abiding, though varying, cause which favours or resists outbreaks of cholera. Poverty, dirt, impure water and air, and other commonly assumed causes, are always present, and certainly have not been proved to be worse in epidemic than in healthy years.

According to Von Pettenkofer, an outbreak of epidemic cholera requires the simultaneous co-operation of three factors: (1) traffic (between healthy and infected places); (2) local and temporal disposition; (3) individual disposition as affecting the specific poison. The poison may be carried by means of soiled linen, various articles of food, excrement, etc. Transportability, however, does not imply contagion, the latter term being applied to poisons which multiply only within the body; the cholera-poison, like that of typhoid, is a miasm, *i.e.* it may be carried, but increases independently of the body. Cholera, in fact, depends far more on the locality which develops the poison than on the carrier of it. But though imported the poison will not always breed; it must find suitable local, temporal, and individual disposition. The influence of locality may be seen in the greater distribution of cholera according to river and drainage districts than to lines of traffic. Epidemic cholera is reported by the Bavarian Commission of 1854 only to have occurred in places situated

on porous ground, permeable to air and water, and in which water could be found at a moderate depth; and places situated on impermeable soil escaped, or only had isolated cases. The influence of the seasons is indubitable. Taking all the cases and deaths which occurred in Prussia from 1848 till 1860, both steadily increase from a minimum in April, reaching a maximum in September, and again declining from that time. Having analysed all conceivable influences which could produce the varying power of cholera, Von Pettenkofer observed that the variations of the ground-water alone corresponded invariably with the known course of the disease: whenever the ground-water is high cholera is low (and also typhoid fever). This correspondence has been so constantly observed that it cannot be a mere coincidence. At the end of eight years the mathematical probability that the connection was casual amounted to 36,000 to one; now it is over 1,000,000 to one, a stronger probability than we almost ever meet with in the daily events of life. The cause of this influence is not clear; Dr. Hime considers that it depends on the more active decomposition of organic matter in the ground, which is evinced by the greater development of carbonic acid in the ground-air at the seasons when typhoid and cholera are most common. Professor Von Pettenkofer courageously applied his theory to cases where the influence of the ground-water must be eliminated, as in ships, and to towns which enjoy immunity. His investigations in both directions make out a very strong case. His examination of the causes of the immunity of Lyons is a model of scientific work.

A vast amount of most valuable information on hygiene, behaviour during epidemics, disinfection, and kindred subjects, will be found in this work, which we cordially recommend to our readers, especially medical officers of health and sanitary authorities. Dr. Hime has done his work well and produced a valuable work. It is illustrated with woodcuts and a diagram. The report on the Vienna Congress is succinct, and useful.

MISCELLANY.

MEDICAL MEMBERS OF PARLIAMENT.—The medical profession is well represented in the Italian parliament, in which the last elections have placed twelve physicians and surgeons, and one accoucheur. The best known amongst them are Signori Strada, Mantegazza, Baccelli, Palasciano, Umana, and Lanza.

We learn from *Nature* that one of the large blue gum-trees (*Eucalyptus globulus*) in the temperate house at Kew is now showing bunches of fruit. These fruits are from three-quarters to an inch in diameter, and are peculiar on account of their hard woody nature, being nearly enclosed by the ligneous calyx, and opening at the apex by valves corresponding in number with the cells.

PRINCE LEOPOLD.—There is much, although not the usual, ground for anxiety, in the text of the bulletins of Prince Leopold's physicians. Hæmorrhage following typhoid fever in an ordinary case is of very evil omen; usually it implies an acute form of the enteric disease, and consequent severe perils in the ultimate results of the fever. Here, however, the fever has been light, and the patient has passed through its singularly regular stages. Prince Leopold has been all his life liable to local hæmorrhages; the hæmorrhage is an accident outside the course of the disease. Its gravity is to be measured by the extent to which it debilitates.

THE HUNTERIAN ORATION.—The oration this year in honour of John Hunter, the distinguished anatomist, will be delivered at the Royal College of Surgeons on Saturday, February 13, by Dr. F. Le Gros Clark, president of the college, and consulting surgeon to St. Thomas's Hospital.

At the annual meeting of the American Health Association, held at Philadelphia on November 10, Dr. Baker, on behalf of the State Board of Health of Michigan, presented a book of specimens of poisonous wall-paper gathered in that State by Professor R. C. Kedzie, of the Agricultural College. Several members spoke of the importance of this subject, and a committee was appointed to make further investigations. Dr. R. C. Kedzie was appointed a member of this committee.

ALCOHOLIC MANIA.—This disease is said to have increased in France to an alarming extent, and is thought to be traceable to the increased consumption of brandy. From a return published on the consumption of this liquor during the last forty years we find that the mean annual amount is stated to have been one litre per head in 1831, and 2.54 litres in 1869. From 1850 to 1860 the mean number of accidental deaths attributable to intoxication has increased in the proportion of 331 to 587, and the number of suicides from 240 to 664.

TREPHINING AMONGST THE CELTS.—Amongst the Celtic bone remains which were found in large quantities in the barrow at the chateau at Meudon, in 1845, M. E. Robert discovered a small round piece of bone evidently extracted from one of the temporal bones of the human skull. M. Robert is of opinion that it was taken from the skull during life to give egress to effused blood or to open an abscess; though he owns that it may have been removed after death as an amulet, according to the practice which has been observed in Mexican sepulchres of later date.

TRANSFUSION OF BLOOD.—The alienist physicians of Italy, who met in Congress at Imola on September 21, 1874, examined and discussed the transfusions performed in several asylums, and especially in that of Alexandria, under the direction of Dr. Ponza, who has reported the cases *in extenso*, together with the method of operation, in a memoir entitled *Della Transfusione del Sangue praticata negli Alienati del Manicomio di Alessandria*. Three transfusions were also performed in the presence of the Congress on the lunatics at the Asylum of Imola, and the members of it passed a resolution to the effect that transfusion of blood from the artery of a lamb to the vein of a lunatic patient, being neither difficult nor dangerous, and being capable of performance with ease and certainty, the Congress believes that the efforts of those who have entered into this new therapeutic plan of treatment should be encouraged, provided they are accompanied with a great deal of prudence, and above all, by an attentive study of the indications for and against it.

THE PROFESSION IN FRANCE.—The number of medical men in France seems to remain stationary. In 1847 there were 10,643 practitioners, or one to every 3,244 inhabitants. In 1866 there were, taking in the annexed departments, 11,525, still, by a singular coincidence, averaging one to the same number of inhabitants above cited. In 1872, when Alsace and Lorraine were lost to France, there were only 10,766 doctors, or one to each 3,353 inhabitants. This dearth of medical assistance is attracting considerable attention in France, and is likely before long, according to the *Revue Scientifique*, to become the subject of legislative interference. The unequal distribution of the available number of medical practitioners renders the situation all the more serious; for instance, in the department of the Seine there is a doctor to every 1,115 inhabitants; whilst in the department of the Morbihan there is only one to each 10,576 of the population; a scarcity of medical aid which is surpassed in the case of one department which rejoices in the medical care of one practitioner only for 11,000 people.

LEAD IN SODA AND SELTZER WATER.—At the second meeting of the North British branch of the Pharmaceutical Society of Great Britain, a paper was read by Dr. Stevenson Macadam, dealing with the question of the presence of lead in aerated waters. After having stated in the outset that so far back as 1871 his attention had been directed to this subject, and that at that time he had discovered that hard waters had a greater power of action upon lead than soft waters, Dr. Stevenson Macadam proceeded to describe the apparatus used in the manufacture of the aerated waters. Regarding the generator of the carbonic acid, he gave it as his opinion that this part of the machinery might be of lead without causing the slightest harm to the manufactured waters; while, on the other hand, the greatest care should be taken that the gas-holders should not be constructed of materials containing lead. As to the receiver, he was sorry to say that in some instances he had found that this vessel, though made of copper, contained a large quantity of bad tin, which in turn was impregnated with lead—a state of matters which of course caused contamination to the waters. So far as the piping was concerned, he held that there was no difficulty in manufacturers obtaining pure tin pipes, while he submitted that the solder used should also be free of lead ingredients. Passing on to explain a number of experiments he had made relating to the question under consideration, the speaker stated that after the fluids had been poured from bottles into lead pipes, and instantly poured back out of the pipes again, the result of analyses proved that there was in aerated waters the tenth of a grain, in lemonade the half of a grain, and in soda and potash water the twentieth part of a grain of lead to the gallon. If the liquids were allowed to remain an hour in the lead pipes, the amount of lead found would be in lemonade ten grains, in aerated waters five grains, and in soda and potash waters two grains to the gallon. In samples sent to him for analysis, Dr. Stevenson Macadam further mentioned, he had discovered the presence of lead to the extent of one grain to the gallon in lemonade, one half of a grain to the gallon in aerated waters, and one-fifth of a grain to the gallon in soda and potash waters—it having been at the same time ascertained that the oil of lemons, used largely in the manufacture of lemonade, generally contained quantities of lead owing to the fact of the vessels in which the oil was stored not being free of that metal.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.: free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, JANUARY 27, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE FORMATION AND TRANSFORMATION OF BONE. BY PROFESSOR R. VIRCHOW.*

(Continued from page 31.)

With regard to this kind of transformation, I have proved the fact, already established by a large number of acknowledged observers, that at the limits of the ossifying part single cells are to be met with, which project half way into the cartilage; so that, while one-half of the cell is to be regarded as a cartilage-corpuscle, the other half remains free, and is surrounded by soft intercellular substance in place of the firm intercellular substance of the cartilage. I have even seen whole rows of these cells, proliferating cartilage-elements, placed so that they were not imbedded at their ends in hyaline tissue and cartilage-corpuscles. It is now imagined that these are wandering cells; that the cartilage-cells have disappeared, and that medullary elements have taken their place.

You understand, that these questions can be solved, for the most part, only by way of interpretation. Processes of this kind cannot be brought under direct observation; you cannot see the cartilage grow and undergo changes under the microscope. But, so far as an unprejudiced opinion can entitle one to an opinion, I must still maintain that, in these circumstances, a direct melting down of the cartilage takes place, and that the same elements pass into medulla, which previously were elements of cartilage. I have even seen how such elements showed divided nuclei; and close thereon I have met with two cells in place of one; so that it seems to me proved that a true formation of marrow takes place through a gradual liberation of healthy cartilage-elements, often accompanied with proliferation: nay, that even red marrow is produced from cartilage. This is certainly in itself a very delicate distinction. You will, perhaps, ask me whether it is so important to know whether the formation of marrow takes place in this or in that way. Let it be agreed (you may say) that medullary spaces are really formed in the cartilage. But in truth it is a great difference, whether the cartilage generates the medullary spaces from itself, or whether it is worn away by an immigration of cells at certain points. We are now in the century of wandering (*Wanderjahrhundert*); and nothing can occur without a locomotion of elements. In regard to this I share in the apprehension of Herr Wolff, that the constant internal revolutions may be a little thoughtlessly applied to the whole process of bone-development. But I differ from him with respect to the assumption of

frequent metaplasas in the interior of bone; and, with special reference to the point now under consideration, my opinion still is that marrow may be produced directly from cartilage, through a melting down of the cartilage and such a change in the intercellular substance, that cells hitherto enclosed within a capsule and in a firm hyaline substance cease to be so enclosed, and come to lie in a quite soft matrix.

Another way in which the formation of medullary spaces and of medulla takes place is from the osseous tissue. With regard to this I will first observe, that the place where this kind of transformation is most usually to be seen, is the compact substance of the bone. To this process belong the phenomena which have already been long regarded as the commencement, indeed, as the ordinary mechanism, of the development of medullary spaces and, later on, of the medullary cavity. The firm cortical layer, *e.g.* of the tubular bone, first becomes porous in its inner layers; small apertures are formed in it and increase until they become medullary spaces; and at last the osseous tissue entirely disappears on their inner surface, and the marrow-substance in them becomes confluent with that of the great medullary cavity.

On this rests the view that the medullary cavity becomes widened at the expense of the former cortical substance, and that the under layers of this substance are destroyed during the growth of the bone. Pathologically, the facts in evidence of this are so distinct, that I know not how there can be any doubt as to the fact of medullary spaces being formed in the places where bone-tissue formerly existed. More difficult is the question, whether the osseous tissue itself produces marrow. As vessels are found everywhere in the compact substance, it is possible that an influence may be exercised by them in the melting down of the osseous tissue, and that an immigration of new elements takes place. In the mean time, we must first understand that the coarse fact exists, that truly compact substance may be changed into spongy. A series of pathological preparations will not only demonstrate this, but will at the same time lay another as yet little known fact clearly before our eyes.

I speak of certain syphilitic processes. I have brought with me some parallel bones (tibiae) presenting the well known syphilitic exostoses, hyperostoses, and periostoses. Syphilitic hyperostosis is a well marked example of supracortical deposit, of a kind to which those who deride apposition can generally take no exception. In hyperostosis, it is sufficiently possible to follow the old limiting line of the compact substance, and to be convinced that, although the thickness of the internal substance has doubled, the medullary cavity shows no difference at this part. Now there are cases, where the whole bone becomes so thick, especially those remarkable cases in which the whole femur undergoes this change, cases with which hitherto there has been a difficulty in dealing, because there has been hesitation in grouping them among syphilitic diseases. On the tibia, partial periostoses are often found, especially at the middle of the shaft. After these hyperostoses, in the course of a certain time and in many cases years, have become quite as firm as ivory, they become spongy exactly in the manner described. Medullary spaces are formed in their interior; the process gradually advances outwards, so that in some cases the new spongy substance nearly reaches

* Read before the Berlin Medical Society, November 25, 1874. (*Berliner Klinische Wochenschrift*, January 4 and 11.)

the surface, and scarcely any cortical matter is left. This spongiosis, *alias* osteoporosis, which makes the bones quite spongy, and which is at first not accompanied by any change in the medullary cavity, belongs essentially to the more advanced stage of syphilitic hyperostosis. It is to be understood as the result of a gradually advancing process, by which the whole bone is rendered lighter and more conveniently borne.

There is scarcely a second example where the process of the formation of medullary spaces from eburnated tissue is so evident; but there are very many analogies. I will especially call attention to the specimens of united fracture, where, in cases of distorted union, the compact substance of one of the portions of the fractured bone has encroached on the medullary cavity of the other. In a preparation of this kind, especially in fractures of the long bones, the following series from above downwards may be distinguished at a certain time; old medullary cavity, callus, compact cortical substance of the lower displaced fragment, and finally the medullary cavity of the latter. We have only to wait, to see how the compact substance undergoes change in the direction of the medullary cavity. If the individual survive, the process of osteoporosis, of which we have just spoken, begins at a later period, and increases until at last the medullary cavities divided by the fracture become united into one by the fusion together of the extensive medullary spaces.

I could quite as easily have brought before you normal bones for the demonstration of these changes; in the meantime, I thought that it would be interesting to you to prove these things for once from a pathological point of view. The same process occurs also in the normal condition. My position is this: marrow is produced at one time at the expense of cartilage, at another of osseous tissue. The marrow replaces the disappearing parts; it fills up the cavities which are produced, and thus we have no vacant spaces, but a changed condition of tissue. It is not unimportant to follow out these processes, when one is occupied with the question of the formation of the spongy substance, or when one goes on further to the consideration of the growth of bone. For my part, I am of opinion that, just as marrow may be produced from cartilage as well as from bone, so also, on the contrary, cartilage very rarely indeed, and bone very often, are formed from marrow; I believe that nothing more than a new transformation is necessary for the direct creation of new bone-tissue from marrow. If you wish for a pathological example of this, I show you here cases of osteosclerosis, where the whole mass of the marrow, even the contents of the medullary spaces, is replaced even to the minute divisions by that eburnated substance which you have already seen to be deposited by apposition on the exterior. When ossification of the marrow takes place in this way, there is first in each case, as I have shown, that thickening and increase of the intercellular substance which, with diminution of the cells, produces the intermediate form to which I have applied the name osteoid. At a later period, this thickened intercellular substance takes up lime-salts, and thus new bone-tissue is directly formed.

I have thus no difficulty, having recognised the possibility of ossification of marrow and of medullification of bone, in explaining great changes in the nature of bone, and I find no contradiction either on theoretical or on practical grounds. Therein I differ especially from Herr Wolff. He holds, not without

well weighed reasons, the opposite opinion, that the inner structure of bone preserves considerable stability, and that its later conditions agree so closely with its former, that they are only to be explained as a simple phenomenon arising, as he concludes, through interstitial growth. I cannot share in this assumption, which is again based on a one-sided examination of macerated bone, deprived of its marrow; when one has to do with bones daily, they are seen to be in fact more variable than women. An old proverb says, 'Varium et mutabile semper foemina;' but it might still better be applied to bones. I might say, that the processes which take place in bone are comparable with geological changes. They are not, as Herr Wolff expresses it, revolutions: they can scarcely be called reforms, so tedious is their progress, so long a time is it before they are complete. But this alteration of construction and absorption, or, as it has been better said, of formation and transformation, assumes a magnitude in bone of which I know no second example in the body. While at first sight bone is a highly conservative substance which apparently resists all changes, and to which we would attribute the most extreme durability in the living body, quite the contrary is the case. A part of the transformation, that which acts on the rough form of the bones, is without doubt assisted by the giant-cells (osteoclasts or myeloplaxes) which sometimes attain such an astonishing size that they occupy almost the entire field of the microscope. They fill up the holes in the disappearing bone. From the often simultaneous processes of decay and formation the most extreme changes often arise. How far these may go in each individual bone, cannot be theoretically foreseen. Herr Kölliker has taken the great trouble of examining each bone of the skeleton in animals, to find where absorption and where formation of osseous tissue takes place.

(To be concluded.)

STURGIS ON THE EXPECTATION OF LIFE IN THE SYPHILITIC.*

Dr. Sturgis premises in his remarks that the data at his command do not allow him to put forward more than an approximation to the truth. Comparing the severity of the disease at the present time with the descriptions of its ravages during the sixteenth century, he concludes that syphilis is far milder now than formerly. To estimate the mortality from syphilis, he collected the numbers of cases entered as syphilitic at four London hospitals—St. Thomas's, St. Bartholomew's, the London, and St. George's during a series of years, with their mortality. He found that forty-one out of 2,938 cases died, or nearly 1.4 per cent. But he acknowledges that these data are little trustworthy, as a large proportion of those treated for syphilis die after they have been lost sight of at the hospital. In New York and in London, the number of deaths registered from syphilis form 0.5 per cent. of the total deaths, while at Philadelphia they are reckoned at about 0.1 per cent. At the General Hospital in Vienna, Zeissl states that 1,097 syphilitic patients were treated in 1862, and that 0.7 per cent. died from syphilis. From these data he thinks an ample margin would be allowed if 2 per cent. of the deaths among the poorer classes and 1 per cent. among the richer are set down to syphilis.

* New York, 1874.

Among the causes of death the author finds 'exhaustion' most frequently assigned. By exhaustion he means syphilitic cachexia, in which the system loses all functional and vital power, and the patient dies slowly inch by inch. But there is little exact information of this kind.

Next he considers the effects of habits, age, occupation, climate, social standing, marriage or celibacy, and physique, in assisting the deteriorating influence of syphilis. Debauchery, dirt, and exposure are well known factors in producing the malignant forms of syphilis. Occupation has no marked influence. Climate, either a very hot or a very cold one, aids the development of syphilitic cachexia. A good social standing, by enabling the patient to obtain a sufficiency of the comforts of life, opposes the influence of syphilis. Marriage, by inducing people to live more regular lives, also tends to prolong life. Age has an important effect. Syphilis, if contracted after middle life, is less readily recovered from than in youth. Death from syphilis takes place far most frequently in infants; next to them in young adults; hence the author concludes that in such persons the disease has been congenital, even when the patient has reached manhood, because he supposes acquired syphilis in the majority of cases would not have had time to kill the patients before the age of thirty. The inherited taints of scrofula or tuberculosis favour the deteriorating influence of syphilis greatly.

Syphilis affects some races more severely than others. It is stated that, besides the well-known examples of the South Sea Islanders and American Indians, the Negroes in America suffer more from the ulcerative forms of syphilis than do the whites.

In considering in what way syphilis does shorten life, the author considers that death is hastened in the following modes; 1. By exhaustion; 2. By rendering its bearer more liable to other diseases, such as inflammation; 3. By favouring structural changes in viscera whereby their function is impeded or prevented.

In considering the expediency of insuring the life of a person suffering from syphilis, no one actually syphilitic should be accepted, because, though in the vast majority of those attacked the virus exhausts its influence without causing any change of structure sufficient to impede the function of any organ, so long as the influence remains the ultimate consequences cannot be foretold. Nevertheless, if the patient have passed through his syphilis, his life may be a good one to insure. But the usual duration of the disease being two years, and two years more being required for observation, the author thinks that four years from the date of his infection in ordinary cases, and three years in cases where the disease has an advanced stage, should elapse from the last symptoms before his life is accepted. For this reason, the date and character of the last symptoms should be carefully ascertained. Again, the absence or presence of a family history of tuberculosis, etc., should be carefully inquired for; but, if the syphilis have been mild, more on account of their tubercular tendency than on account of their syphilis. Patients, the subjects of inherited syphilis, should be avoided utterly, and their lives taken at no rate.

[This epitome of the current knowledge of the effect of syphilis in shortening life is acknowledged by the author to have little worth beyond showing to those seeking for precise information on the value of lives of persons who have had syphilis, that our

knowledge is very meagre and most inexact. There are three causes which render any calculations, based on the returns at present accessible, fallacious.

1. The proportion of cases of visceral syphilis to the whole number of persons who suffer from syphilis has not yet been worked out.

2. The proportion of disabling disease which has originated in syphilis, is also at present far from being determined or agreed upon.

3. The returns of the predisposing causes of all deaths are at present too imperfect for a trustworthy estimate to be drawn of the amount of mortality produced by syphilis, even when the mode of death, were it known, is one of the recognised effects of that disease.—*Rep.*]

BERKELEY HILL.

HILDEBRANDT ON THE TREATMENT OF UTERINE FIBROMA AND MYOMA BY HYPODERMIC INJECTIONS OF ERGOTINE.

Professor Hildebrandt, in the *Beiträge zur Geburtshilfe und Gynäkologie*, Band iii. Heft 2, 1874, remarks that recent literature has been lately very full of repeated trials of hypodermic injections of ergotine for the treatment of uterine tumours. As a rule, the result has not been favourable. Failure seems to have arisen chiefly from three causes: the extreme pain endured by the patient; phlegmonous inflammations and abscesses; and, in one case, poisoning. The strongest argument that has been used against it is, that those who have the hardihood to go through all the suffering have derived no benefit whatever. As to Dr. Hildebrandt himself, his experience has differed in no wise from that previously reported (*Berliner Klinische Wochenschrift*, no. 25, 1872), and he is perfectly satisfied with the results, which go to substantiate his previous assertions.

First objection: *Pain*.—The solution of ergotine now employed has 13 parts of water to 3 of the extract of ergot, and 2 of glycerine. It causes less pain than when the quantities of water and glycerine were equal. The glycerine is added to prevent the formation of fungi. With this preparation, the pain is not greater than that usually experienced with the injection of quinine. The first applications are the most painful; the region of Poupert's ligament is the most sensitive spot, and that of the umbilicus the least so. There are two distinct varieties of pain; the first an immediate one, the effect of irritation to the cellular tissue, lasting a couple of hours; the second coming on later, and continuing for about an equal time, arising from contraction of the uterus. The latter kind of pain is essential to the success of the operation; the more severe it is, the more likely the desired effect will be obtained. Wernich's solution produces this pain also. The more deeply the needle is driven, the less intense is the first variety of pain.

Second objection: *Phlegmonous inflammation and abscesses*. Dr. Hildebrandt has never seen these accidents follow his own injections, and only twice where his assistants had operated; and this out of over 1,000 hypodermic injections. These complications are believed to depend upon not inserting the needle deep enough; he passes the cannula at least two-thirds of its depth, and does not mind injecting the fluid into the muscular tissues. The skin and its mediate superficial layer of cellular tissue should be thoroughly cleared. The experience of Langenbeck,

Awater, and Löhlein, coincides with his own, both as to this method of diminishing the pain, and obviating the occurrence of abscesses.

Kleinwächter's case of *poisoning* arose from the solution being too strong, three and a half parts nearly of ergotine to two of water and two of glycerine. The symptoms were analogous to those of morphia poisoning, 'deep stupor, reduction of temperature, pulse 140.'

Against the negative results of other investigators he places the positive benefits obtained, as observed by Hermanides, Eggel, Bengelsdorf, Cl. Mayer, Keating, Hennig, and Wernich; the latter having seen the treatment check hæmorrhage in the majority of cases even after five or six injections, where it had been used solely for that object. Scanzoni writes him privately under date of March 30, 1874, that he is, as a whole, completely satisfied with his results, although he cannot flatter himself with ever having seen the entire disappearance of the tumour. He has used it in seventeen cases of large and small fibromata, the injections being persevered in for months. In one instance, a tumour midway between the navel and pubes diminished to the size of an orange after forty injections. In a case of flooding from fibroma, it was arrested after the seventh injection. Dr. Burow writes privately to say that in one case a fibroid of the size of a child's head was reduced in three months to the size of an orange, with complete cessation of menorrhagia.

Dr. Hildebrandt now gives sixteen fresh cases, which occurred either in his own practice or under his immediate supervision, and divides them into three classes:—1. Removal of the symptoms, with reduction of the tumour; 2. Marked improvement of the symptoms, with slight reduction of the tumour (these were partly his own and partly others); 3. No effect either on the symptoms or on the tumours.

I. Removal of the Symptoms, with Reduction of the Tumour.—In the first division there are five cases, in women respectively of the ages of forty-three, thirty-four, twenty-eight (single), thirty-seven, and thirty-six years. In the first case, the tumour reached to the umbilicus; the uterus was moderately thickened and elastic. At the end of fifty injections, during two months, the tumour had receded to about the size of a three-months' gravid uterus. In the second case, the fibroma, about the size of a man's fist, was felt to be in the right side of the abdomen. With fifty-five injections, during three months, the tumour had ceased to be felt through the abdominal parietes. The small subperitoneal tumours which were noted before the operation, were in no wise affected, except being more prominently felt. In the third case, that of a single woman, the tumour was nearly up to the navel; it was elastic, and distinctly demarcated from the surrounding organs. Twenty-six injections, during two months, diminished the tumour so much that its apex could be felt on a level with the pubes. At the request of the woman, the treatment was not continued. In the fourth case, the uterus was deeper than normal in the pelvis; the infravaginal portion of the cervix was not altered; the uterus was about the size of an apple. The uterine sound passed in $9\frac{1}{2}$ centimètres (about $3\frac{3}{4}$ inches). There was profuse menorrhagia. In less than two months, after sixty-two injections, the uterine sound passed in $7\frac{1}{2}$ centimètres (about 3 inches), and the body of the uterus was about the

usual size of a multipara. In the fifth case, the uterus was universally enlarged to about the size of a small apple, with a fibroma in the wall on the right side; menstruation was excessive. With fifty-five injections, at intervals of two or three days, only half of the amount of solution being employed at times, on account of the pain, the uterus remained the same; but the tumour entirely disappeared. The tumour might have been only an exudation.

II. Marked Improvement of the Symptoms with Slight Reduction of the Tumour.—Case 1. A woman (age not given) had menorrhagia of two and a half years' standing. The fundus of the uterus was about three finger-breadths above the pubes; a large fibroma was diagnosed on the right side of the uterus, extending into the cavity; it was firm and smooth on the surface. Sixty injections were made during nearly three months. At the end of the time the uterus was found to be on a level with the pubes, the menstruation had become normal, and the woman was able to move about again.

Case 2. The age of this patient is not given. The catamenia were regular as to time, but excessive in quantity and clotty. The uterus was as large as at the fourth month of gestation, anteflexed, with a subperitoneal fibroma as big as an apple in the left and upper side; an intrauterine fibroma was also believed to exist. The uterus was firmly elastic. Fifteen injections were given, one every second day; the treatment could not be borne longer on account of the suffering induced. Menstruation became normal.

Case 3. The patient, aged thirty-seven, had menorrhagia, with regularity, however, as to time. There were two uterine tumours; one subperitoneal on the left side; the other, a larger one, intramural, in the posterior wall. Both were diagnosed as fibromyomata. Daily injections were used for a month, with an interval once of four days, from some phlegmonous inflammation showing itself around the seat of puncture. The next period was better, the tumour was slightly less, and perceptibly so; it was more readily felt, and more distinctly demarcated from its uterine parenchyma.

Case 4. In this woman, aged thirty-five, there had been excessive menorrhagia for the last two years. A large fibromyoma was distinctly defined, growing in the anterior wall, expanding the uterus above the pubes to about the size of the fifth month of gestation, at the same time descending deeply into the pelvis. Forty-seven injections were made in three months. The menses, which previously appeared every fourteen days, now had an interval of twenty-one and twenty-three days; their quantity was more normal, but they were still profuse. The uterus was a little smaller.

Case 5. In this patient, thirty-four years old, the catamenia appeared for the last twelve months every three weeks; they were excessive, with expulsion of clots. A fibroma about the size of a child's fist was diagnosed in the left wall of the uterus. Forty injections were made in three months. The fibroma became one-third smaller, the menses ceased, and pregnancy occurred, which pursued a normal course.

Case 6.—A single woman, age not stated, had extremely profuse, painful menorrhagia every fourteen days, lasting eight or nine days. She had continued in this state for the last six years, and was extremely blanched. The uterus was anteflexed, broad, and extending a little above the pubes; the tumour had a firm consistence, with a smooth surface. Twenty-two injections were made during nearly two months.

She became better in every respect; the catamenia appeared with an interval of twenty-nine days, continuing seven days. The injections were continued with good effect on the hæmorrhage and benefit to the patient, without, however, producing any perceptible diminution of the tumour. This was in 1872. During the winter of 1873-74, in spite of the injections, the hæmorrhage became freer, and for the time profuse. What was the exact cause of this return of hæmorrhage the writer cannot say, but he thinks that the tumour (submucous?) might have descended, become seized in its downward course, which occasioned a temporary increase of bleeding.

Case 7.—The patient was single, aged forty-seven. The uterus was of the size of a man's head; menorrhagia was excessive, and she had leucorrhœa. Twelve injections were made. The menstruation was moderated, the periods being two days shorter. The tumour was unchanged; the fluor albus remained the same.

Case 8.—This patient was aged thirty-five, with profuse menorrhagia every three weeks, of eight or ten days' duration. The fundus was felt midway between the navel and pubes; it was globular and firmly elastic. The cervix was patulous as far as the internal os. Twenty-five injections were made. The next period lasted nine days, but was moderate in quantity. The general condition was benefited. The uterus was two finger-breadths above the pubes.

Case 9.—This woman was thirty-eight years of age; she had suffered from excessive menorrhagia for seven years. The last two years the menses had appeared every fourteen days, and there was a continuous intermediate sanguineous discharge. A slightly elastic tumour of the size of a fist was felt in the wall of the anteflexed uterus. After fourteen injections menstruation became normal, for the first time for years. The tumour was somewhat smaller. Notwithstanding every precaution, phlegmon occurred twice in this case.

III. *No Effect on Symptoms or on Tumour.*—Case 1. The patient, thirty-seven years old, had a painful tumour on the right side of the abdomen. There was no leucorrhœa. Two tumours were found in the uterus; one of the size of an apple in the anterior vault of the vagina connected with the anterior wall of the uterus; a second somewhat smaller, in form like a normal uterus, seated on the right side of the walls of the uterus. Daily injections were made for fifteen days without producing the slightest alteration on the tumour. Case 2. The uterus was of the size of a man's head, with even surface and of hard consistence. There was profuse menorrhagia with faintings. In Case 3, an old submucous fibroma was diagnosed; the patient derived not the slightest benefit from thirty injections.

Dr. Hildebrandt has again seen the first of his former published cases, after a lapse of two years. She came into the hospital with a five months' child at the breast. He examined her, and found the uterus of normal size, without a trace of any abnormalities. In Case 5 of the same series the benefit continues, but the uterus is no smaller.

He believes it is essential, in order to obtain a successful result, that the tumour should be compressed by protracted contractions of the uterine walls. As, in neoplasms of other parts of the body, absorption can be produced by prolonged instrumental compression, so also may fibromyomata be reduced in size by similar compression by a tetanically contracted uterus. Whether the action of the ergot in

causing contraction of the uterus and thereby compressing the tumour is the only way in which it operates, remains doubtful. In some cases, he is under the undoubted impression that the tumours soften before they lessen. If this softening were always present, it might be explained by supposing that the tumours, through an excess of blood in the veins, and a diminution in the arteries, as seen by direct experiment of Wernich, were gradually disintegrated. He protests against having ever maintained or believed that every fibroma of the uterus was capable of dispersion by ergotine injections.

The consistence of the tumour is all important. An old impoverished fibroma, consisting chiefly of thickened connective tissue, is as unlikely to be absorbed as a calcareous mass. If the ergot increase the hæmorrhage and discharge, it is probable that it does so by the uterine contractions causing a narrowing of the vessels. This is generally found to be the case in aged persons, the reverse, however, with the young; with the latter the tumours are vascular and loose, with muscular fibres. The most favourable cases are those which resemble in form and consistence a tense elastic cyst, which was the case with his first published case.

Energetic uterine contractions are essential to success; hence the uterus must be healthy and capable of contraction. Thin muscular walls are less fitted, as seen in some subperitoneal and submucous fibromata of large size, where the uterine walls are much expanded. In the intermediate sized tumours, there is more risk of indurations and exudations into the parenchyma than there is from thinning. The cases the least suited are those where there have been some chronic parenchymatous metritis or perimetritis and parametritis. These conditions should be first cured before attempting injection of ergot. Lastly, the most favourable position is immediately under the mucous membrane—the muscular layer that covers it being perfect. In the middle of the uterine walls, it is less favourable, but least of all when subperitoneal. In these latter kind of cases he has at times observed the tumour pushed out, and thereby rendered more prominent, by injections.

In order to promote rapid absorption of fibromyomata the following conditions are essential.

1. Their seat should be submucous.
2. Their consistence should be of a tense, elastic, muscular character.
3. The uterine walls should be healthy, contractile, not thinned by stretching, not unyielding through exudations, and the uterus free from perimetritis and parametritis.

He adds that whoever thinks he will cure the symptoms and remove the tumours by a few injections, greatly errs. At least from twenty to fifty or more are absolutely necessary to obtain favourable results.

W. C. GRIGG, M.D.

PEPSIN OF COMMERCE. BY CHARLES SYMES, PH.D.

In the spring of last year I conducted a number of experiments on commercial pepsins, with a view of ascertaining their relative digestive power, and published the results in the *Pharmaceutical Journal*, vol. iv. p. 1. I was prompted to undertake these chiefly by the fact that some medical men prescribed and valued pepsin, especially as a restorative agent, but could not get uniformly good results; whilst

others, disappointed by its uncertain action, ignored it in their practice. The problem very naturally presented itself—Does the fault lie with pepsin proper, or with the manner in which it is prepared? My conclusions pointed to the latter, for, whilst some samples were all that could be desired, others were sadly deficient in activity.

Pepsin has now become officinal, and we see the value of this at the outset, not so much on account of the process given (which is a very crude, somewhat uncertain, and wasteful one), but from the fact of having a recognised test to which any article sold under this name is amenable. Previously to this, each experimenter or manufacturer used his own test, which although perhaps good, was certainly arbitrary.

The colour of pepsin will always vary somewhat when prepared by the British Pharmacopœia process; we can, therefore, afford to dispense with this portion of the specification or description. The test given is sufficiently severe, as the best samples I have examined barely come up to its requirements; it is as follows.

‘Two grains of it with an ounce of distilled water, to which five minims of hydrochloric acid have been added, form a mixture in which 100 grains of hard boiled white of egg, in thin shavings, will dissolve on their being digested together for about four hours at a temperature of 98°.’

This is very simple, and yet for comparative results requires great care. Two grains of pepsin only being used requires exactness in weighing; the acid must be measured in a narrow tube graduated to single minims, and the temperature 98° to 100° must be kept constant during the whole of the operation; at 90° digestion goes on much more slowly, at 100° more rapidly, whilst at 120° the action of pepsin is destroyed. The maintenance of an even temperature is best accomplished by the use of a hot-air bath fitted with Benger’s improved automatic regulator, in which the expansion or contraction of the heated air operates on a column of mercury which regulates the supply of gas to the burner.

A few pharmacists themselves prepare the pepsin they dispense, but the bulk of that in general use is prepared by certain well-known manufacturers. Nine samples of such were taken, and one was carefully prepared from a fresh pig’s stomach according to the British Pharmacopœia directions. Of the ten samples, six had been prepared by this process or by some slight modification of the same; two by Scheffer’s process of precipitation with common salt, drying, and mixing with sugar of milk; and two were starchy pepsin. All were subjected to the pharmacopœial test under the same conditions and at the same time, the experiment being repeated for confirmation. Of the 100 grains of coagulated albumen digested with two grains of each sample, the following quantities remained undissolved after five hours.

No. 1	1½ grains.
“ 2	2½ ”
“ 3	6 ”

Here we have considerable discrepancy it is true, but from experience I am able to testify to a considerable improvement in the bulk of pepsin now

used as compared with two years since. I believe, also, that Nos. 1 to 6 are much more largely dispensed than the four latter; they were all pepsins from the pig; indeed, I fail to see why the British Pharmacopœia states that it might be prepared from the sheep or calf also, and yet requires it to answer to the same tests.

In conclusion, allow me to suggest the desirability on the part of the profession to prescribe *pepsina porci*; and as alcohol in any form, even when diluted, has a prejudicial influence on pepsin, the vinous solution is an undesirable form for administration. It should be given either in powders, pills, or elixir—the dose of the latter being one drachm.

BAER ON THE PROVISION FOR LUNATIC CONVICTS.

At the October meeting of the Berlin Medico-Psychological Association, Dr. Baer read a paper on the ‘Provision for Lunatic Convicts.’ The proportion of insane to others in prisons and convict settlements is variously estimated. Thus, Léut reckons that in France it is two per cent.; Gutsch, in Bruchsal, gives it as three per cent.; and Delbrück, of Halle, five per cent., the latter probably representing best those who from one mental infirmity or another require special treatment. This large percentage of insane among criminals is not surprising when one regards their descent, development, education, and conduct when at large and in prison. Of the 5,377 men and women incarcerated in Prussian prisons in 1871, there were 5,096 children left outside, part of whom would certainly descend to crime, stamped with the expression of allied crime and insanity to which fate had doomed them. Bred up as they are in crime, and leading irregular and loose lives, the time spent in prison is the only one when they remain quiet; but this again is so abnormal and so opposed to proper development, that it not only quickly evokes any latent disposition to insanity, but actually creates a predisposition to it. Many prisoners are already insane when they begin their evil career, and their punishableness is never questioned in court; among others the intellectual state is so doubtful, the causes of their irresponsibility are so hidden, that they are committed to the most complete sentence though sent to prison under modified conditions; others again exhibit such a mixture of criminal appetites and diseased impulse, that their punishment is well deserved. The conduct of all when in prison becomes sooner or later such, that their banishment from the institution is as necessary as it is desirable. Taking five per cent as the number of these persons, it appears that in Prussia, in December 1871, there were 1,100 of them. Should these persons be retained in correction-houses, where an iron discipline, unyielding obedience, absolute abnegation of will and subjection to rules must be enforced, where fear and terror must bridle the evil elements? Can the insane tolerate the heavy weight of such regimen? Even though the acute cases of mania, the utterly demented, the paralytics in the later stages, and so on, are treated in the general hospital of the prison, yet the chronic cases, the recurrent insane inmates, the epileptic and the imbecile, cause much embarrassment to the administration. They cannot always remain in the hospital, and they have no special means of occupation and diversion. In the workshops they are made sport of, whilst many are looked upon as malingerers, and

when the presence of insanity is recognised it has become incurable. For several reasons it becomes necessary to remove these persons; first, on legal grounds, all who are without doubt insane; secondly, from precautionary motives; thirdly, for reasons of economy. In making provision for this condition of things, it must be held in mind that the prisoner must be capable of immediate removal into an asylum, to effect which the number of committees must be reduced and the asylum must not be too far distant; next the asylum must be placed absolutely under the control of an alienist, and the building must have no more of the prison about it than is absolutely necessary. The ordinary asylums do not suffice for the insane of the general population, and are not adapted for insane convicts, who soon club together and require strict surveillance. Many asylum authorities have spoken against the reception of these persons, and will do so more loudly if all descriptions of insane convicts be sent to them. As in England, special asylums might be erected, but in them criminal lunatics and lunatic convicts are associated. The former class, however, is only suitable for an asylum, for they never were criminal and cannot be punished. To erect special asylums for insane convicts alone is too dear, and is unadvisable on financial grounds. The only thing left is to add to lunatic institutions or penal settlements a sufficiently large block for the insane convicts. For practical purposes a 'lunatic prison' would be most convenient. Close by the prison, and under the same administration, the 'asylum' part, under the superintendence of a physician skilled in mental diseases, must consist of two divisions—one devoted to the really sick, and provided with all the appliances of an asylum, the other set apart for the recurrent cases, imbeciles and others who require supervision and a milder discipline than the prison can afford. Every doubtful case of insanity, all insane in the widest acceptance of the term, all malingerers should be sent here, so that in the ordinary prisons the acute cases only would remain until they could be taken elsewhere.

T. CLAYE SHAW, M.D.

PATHOLOGY.

FRIEDLÄNDER, WALDENBURG, ZUELZER, ETC., ON THE INOCULATION OF TUBERCLES.—In the 47th session of the Association of Naturalists and Medical Men at Breslau, Dr. C. Friedländer, of Strasburg, made the following communication (*Berliner Klinische Wochenschrift*, November 2, 1874). Villemin and others have induced disease by introducing bits of cheesy matter from tuberculous subjects, and other foreign materials, even caoutchouc, under the skin, or into the serous cavities of animals; as well as by injecting the cheesy matter into the blood-vessels. This is called tuberculosis, and from this etiology conclusions as to tuberculosis in human beings have been freely drawn. It is quite true that there are many points of resemblance between the two affections; yet, in a clinical point of view there are some striking differences. Friedländer injected 20, 30, or 40 cubic centimetres of a fine emulsion of cheesy substance from human bodies into the external jugular vein in twelve dogs. They were quite well after the operation; the wounds healed; only one died from an accident; the eleven others continued well nourished, became fatter, had no fever nor any other

disorder, till they were killed three or four weeks after operation. In ten of these eleven there were found in the liver very numerous little nodules, gray, transparent, of the size of a pin's head; the larger ones opaque in the centre, resembling miliary tubercles. These bodies were constantly present in the spleen, not always in the lungs or kidneys, not at all in the eyes, pleura, or pia mater, only a few in the peritoneum, and those near the liver. Those which were not degenerated in the centre consisted, as shown by the microscope, of an accumulation of round cells, of tolerable size, without any intervening substance; and for the most part the periphery only was supplied with blood-vessels. The opaque centres consisted of cells which had undergone fatty degeneration. The nodules in the lungs consisted of the air-vesicles filled with cells of unmistakably epithelial type; what Buhl calls lobular foci (*Heerde*) of desquamative pneumonia. Small collections of cells were also found between the bronchi and the vessels; but nowhere any formation of nodules in the connective tissue, nothing except such interstitial formations as are common in pneumonia. The disease, thus induced by the experimenter and others in dogs and other animals, is essentially different from human miliary tuberculosis, for the latter is a severe febrile affection, and there are other organs affected beforehand in human beings which escape in dogs—for instance, the peritoneum, eye, and pia-mater. Human tubercles are never supplied with blood-vessels. Giant-cells occur in them, not in the animals experimented on. The things are then not identical, and there is probably great difference in their etiology. In the experiment with India-rubber mentioned above, if the water and India-rubber be previously put into absolute alcohol before being introduced under the skin, or into the peritoneum, the wound heals well, and no 'tubercles' are produced. The cheesy abscess, and so-called tubercles are the simple sequel of a certain kind of foulness (*Unsauberkeit*, lit. impurity). It is, therefore, not safe to draw any conclusions as to human tuberculosis from these experiments. Professor Waldenburg said, *inter alia*, that it was not true that giant-cells were never found in the inoculated tubercles. With Virchow, he believed these giant-cells were not the specific element of true tubercle. Klebs, Hering, and himself, had all seen giant-cells in inoculated tubercles. It was incorrect to say that the animals did not die of the inoculations; in fact, death was more common than recovery in his own experiments. The distribution and structure of these and human tubercles were almost identical. Waldenburg had seen animals become extremely emaciated after the inoculation, and die with large cavities in the lungs surrounded with miliary tubercles, which were also present in the pleuræ, liver, spleen, kidneys, peritoneum, etc., just as in men. The distribution doubtless varied with the site of the primary focus and its extent, and with the kind of injection. Yet, whether men or animals are concerned, the lungs and the liver suffer most. It is well to be exact and critical, but not too sceptical. Dr. Birch-Hirschfeld thought dogs bad animals for experiments; he could never develop tubercles by introducing clean India-rubber into the peritoneum. Professor Friedreich drew attention to the great need for clinical observation in these experimental cases. We are in danger of falling into old errors again about specific elements in tubercle. He had found these giant-cells in typhoid products, and in leukæmic nodules when no tubercle

was thought of. Professor Zenker said these giant-cells were sometimes present in human tubercles, sometimes absent. On this account E. Wagner gave the name of lymphadenomata, in order not to exclude nodules otherwise characteristic from being classed as tubercles. It would, perhaps, be as well to divide tubercles into giant-celled tubercles and dwarf-celled tubercles—*tuberculum giganto-cellulare*, and *tuberculum nanocellulare*. How cautious one ought to be was well shown by the case of a wether sheep which had hydatids of the lung; for, starting from the cheesy wall of the sac, the pleura was infiltrated with most minute but exquisite giant-celled tubercles—the product of infection. Yet the animal was fat, apparently healthy, and had no appearance of dying from tuberculosis. It would not do for us to totally reject all the lessons taught by experiments.

Dr. Zuelzer (of Berlin) from his own experiments and those of Gscheidlen and Traube on putrid intoxication, and the innocuity of artificially developed bacteria, could confirm the statement that various animals, dogs, rabbits, etc., could bear very well the introduction of large quantities of *Bacterium termo*. But the moment one added to these innocuous substances any putrid poison (septic material) the symptoms were entirely altered. Septic or pyæmic symptoms, often somewhat complex, immediately set in. If the matter were introduced into the lungs, then pneumonia was set up, and in the centre of these pneumonic foci there were masses of granular and staff-shaped bacteria. He found the lungs of such animals when killed, studded with tubercles, in larger or smaller numbers.

Dr. Friedländer said he had experimented on other animals besides dogs—such as guinea-pigs, rabbits, etc. He thought too much attention had been given to mere morbid anatomy and histology in these things. We must not be deceived by mere superficial or partial resemblances. Undoubtedly there are cases of miliary tuberculosis without giant-cells—only collections of small granules, so to speak, a sort of pretubercular formation. The views he had expressed were very similar to those published by Friedreich. The production of tubercles by introducing India-rubber into the abdominal cavity is closely connected with Zuelzer's experiments just related, and also with those of Burdon Sanderson.

W. BATHURST WOODMAN, M.D.

CLouston ON A FIBRINOUS SUBSTANCE IN THE PIA MATER OF THE INSANE.—Dr. Clouston has a note in the *Journal of Mental Science* (January, 1875), on the occurrence of an organised fibrinous substance formed during life in the veins of the pia mater and brain in those dying during the 'typhoid' stage of acute insanity. A female was admitted in a typhoid state, after a short attack of acute maniacal excitement. She was almost comatose, being only roused on one or two occasions during the two days she lived. The pulse was 120, very weak; temperature 103° 8'; the face and neck were dusky and flushed, apparently from vaso-motor paralysis of all the branches and capillaries of the external and internal carotids. She died comatose. At the *post mortem* examination, there were found in the veins, both small and large, of the pia mater, small white pearly-looking bodies, that appeared at first like limited white thickening of the venous coats, but were found to be masses of organised fibrinous material. In many places they were attached to thin strings of the

usual *post mortem* clot, and the difference between the two structures was very great. A microscopic examination showed this still better. Instead of the ordinary white corpuscles, caught up in the meshes of innumerable fine fibres of white *post mortem* blood-clots, those masses consisted of bodies like the white blood-corpuscles, but much larger, with distinct nuclei and nucleoli, and, instead of the fine linear fibres, there were fusiform cells cohering strongly, among which those bodies lay in regular parallel rows. The whole of the brain was dusky and congested, with much blood-crystalline matter through it. The cells of the convolutions were very granular.

Dr. Clouston has since met with the same appearances, in a less degree, in a general paralytic, who died comatose in a congestive attack.

Is it possible, he asks, that in these cases the vaso-motor paralysis and blood-stasis, which form so essential a feature in the typhoid condition of acute insanity and the congestive attacks of general paralysis, had gone on to a still further stage, when the white corpuscles began to adhere to the inside of the walls of the vessels, gradually accumulating and becoming organised into the masses described?

G. FIELDING BLANDFORD, M.D.

COLOMIATTI ON TUBERCLE IN THE GANGLIA OF NERVES.—In the *Gazetta delle Cliniche* of November 17, 1874, Dr. Colomiatti publishes a brief preliminary communication on the occurrence of tubercle in the ganglionic nervous system, promising more complete details at a future period.

In the body of a girl who had died of diffuse tuberculosis, he found a nodule of the size of a vetch, mostly caseous, in the last left dorsal ganglion but one of the great sympathetic, a similar nodule on the communicating branch between this ganglion and the one above it, and another on the last left dorsal branch of the spinal system communicating with the sympathetic. Microscopic examination showed that these nodules were tubercular; tubercles were found in the connective sheath of the ganglion, and in the perineurium of the above-named nerves, projecting inwards towards the nerve-elements. There were also tubercles in the interior appendages of the sheath of the ganglion.

In a lady who died of pulmonary and intestinal tuberculosis, and also during life had violent and continuous intercostal neuralgia on the left side, Dr. Colomiatti found at about the middle of the part corresponding to the neuralgia several nodules, almost all of cheesy consistence, involving the nerves and vessels. These nodules were tubercular; tubercles were also found in the cellular sheath of the vessels, and in the perineurium of the nerves.

MEDICINE.

LEREBoullet on BRONCHIAL ADENOPATHY.—Dr. L. Lereboullet calls attention, in the *Gazette Hebdomadaire* of October 16, 1874, to the symptoms by which the existence of bronchial adenopathy may be recognised, and to the foreseeing of the complications to which hypertrophy of the bronchial glands may give rise, so as to prevent the accidents which may result from it.

A very few years ago, the symptoms of hypertrophy of the bronchial glands were unknown. It is true that this lesion had not escaped the attention of pathologists. Every one who had made *post mortem* examinations of consumptive patients had found that phlegmasia of the intrathoracic lymphatic glands was one of the most common lesions of pulmonary tuberculation. Many medical men who specially devoted themselves to the study of the diseases of children had noted the commonness of these glandular congestions in scrofula and tuberculos. Military and naval surgeons, especially MM. Marchal (de Calvi), Daga, L. Colin, Le Roy de Méricourt, Fonssagrives, etc., had laid stress on the common occurrence of bronchial phthisis, or had reported cases of patients who were unable to resist the accidents brought on by tuberculos of the mesenteric and thoracic glands. Finally, in a certain number of cases scattered through the medical journals and the transactions of learned societies are related the accidents which may be occasioned by compression of the great vessels, the trachea, the bronchi, and the pneumogastric nerves. MM. Woillez, Daga, and Gueneau de Mussy specially, have helped in making this disease known. In analysing M. Fonssagrives' interesting memoir, M. Woillez described the tuberculous or melanotic enlargement of the glands arising from cancer or leucocythæmia, and was one of the first to point out that the disease might be recognised by a simple weakening of the vascular murmur.

Summarising and interpreting with much care and clinical acumen the cases published by his colleagues in the army and navy, and comparing them with those which he had himself collected, M. Daga wrote in 1866, an almost complete history of the disorders which might be brought on by congestion of the bronchial glands. Finally, M. Noel Gueneau de Mussy, in his *Clinique Médicale*, 1874, carefully pointed out, in a series of most important memoirs, the anatomical relations of the intrathoracic glands, particularised the symptoms by which their enlargements might be recognised in life, and, by laying stress on the relations which exist between bronchial adenopathy and various diseases of the respiratory system, showed the importance of the pleximetric researches which he had been the first to undertake. It is, therefore, possible, at the present time to summarise all the anatomical, anatomo-pathological, and clinical studies published during the last few years, and to draw attention to a

disease which is but little known, because the physical signs which characterise it are but too often neglected. If it were always true, as MM. Marchal (de Calvi) and Daga believed, that hypertrophy of the thoracic glands is a progressive and mortal disease, the serious complications, such as dropsy, dyspnœa, asphyxia which follow in its wake and which would have been more specially described by early observers, would without doubt have been more often pointed out. The methods of investigation would have been brought to greater perfection, and efforts would have been made to recognise so serious a malady from the commencement so as to prevent it. On the contrary, it frequently occurs that, silent in its progress, evolving itself at the same time as the pulmonary disorders which it helps to complicate, bronchial adenopathy is only recognised by the physical signs which characterise it. All the functional symptoms may be wanting, because the hypertrophied glands do not exercise any pressure over the neighbouring organs. The facts collected and cited by M. Baréty in his lately published work *Sur l'Adénopathie Bronchiale*, in fact show that, out of 101 cases of hypertrophy of the glands found on necropsy, the trachea or the bronchi were compressed by the tumour in only thirty-two instances, in five the superior vena cava, and the aorta in eight. In five instances the pulmonary arteries were adherent to the glands, or were compressed by them. The pneumogastric nerves were in twenty-six cases found enclosed in the glandular tumour or disorganised by compression. The phrenic nerves were affected in only eight instances. In the greater number of cases in which the neighbouring organs were compressed, it was found on *post mortem* examination that the size of the glands had materially increased.

It is in these cases, which are unquestionably the most numerous, that it is important to have resort to the methods of pleximetric exploration advised by M. Gueneau de Mussy. It will, therefore, be well to consider what percussion and auscultation indicate in relation to the extent and gravity of the hypertrophy of the bronchial glands. When the back part of the thorax is percussed in a healthy and well-formed man, we find that, if the arms be brought forward and the head bent down on to the breast, percussion of the interscapular region will obtain a much clearer sound than that induced by percussion of the superior and inferior spinal regions. From the third or fourth dorsal vertebra to the base of the chest, the deep lugubrious sound recalls the pulmonic sound given by percussion of the sternum. Above, the sound is less sonorous and higher pitched, but resistance to the finger is less marked, and it is easier to find in that than in the superior spinal region those differences of sonority and elasticity which may be brought on by pathological changes. To obtain at all precise results we must, it is true, so place the patient as to project the two shoulders forward. We must percuss strongly enough and without stiffening the wrist, we must multiply the explorations and not come to any conclusion until we have verified the same facts on several occasions.

Then only, after having trained ourselves to appreciate the results given by percussion in the interscapular region in normal conditions, which vary in different cases, we may rely on being able to recognise the differences of elasticity, sound, or pitch, which would escape an insufficient or inexperienced exploration. In the majority of cases in which Dr. Lereboullet has

believed that he has recognised hypertrophy of the bronchial glands at the commencement of pulmonary tuberculation (see his *Recherches cliniques sur l'Adénopathie bronchique*), he found a very dull sound, with strongly marked resistance to the fingers, in the superior interscapular region, along and outside the vertebral column.

This dulness, which for the most part cannot be considered as depending on induration of the pulmonary tissue, at times extends over the whole of the region comprised between the vertebral column and the spinal edge of the scapula. Percussion of the superior sternal region on the plane of the first division of the sternum and in the vicinity of that bone, may give modifications of sonorousness. M. Gueneau de Mussy says that, in order to ascertain them, we must for comparison percuss the two halves of the manubrium of the sternum, the first two chondro-sternal articulations on each side, the sterno-clavicular articulations, and the inner portion of the first two intercostal spaces.

M. Fossagrives, whilst asserting that percussion only gives negative results, had pointed out a fact of this kind. Sometimes even the hypertrophy of the anterior glands is very marked. Thus in one of Dr. Marchal's cases the existence of a mass of glands was pointed out which, thrusting the sternum forward, made its way out by a movement of expansion the moment the thorax was opened. MM. Daga, Woillez, and Fossagrives have also discovered that the glandular tumour may give rise to an arching of the sternum. M. Baréty affirms, and it has also been remarked by other observers, that percussion of the superior sternal region would give more certain and constant results than percussion of the interscapular region.

Adenopathies are very common and very fully developed in tuberculous cases, and, especially in soldiers and children affected by tuberculous, the mesenteric glands and those of the thorax are often affected from the outset of the disease; and, as M. Colin has observed, the congestion of the glands appears to precede the evolution of tubercle. In the phthisis of soldiers, the glands most frequently attacked are those which occupy the hilus of the lung or the bifurcation of the bronchi; it is, therefore, easy to understand how in these cases percussion of the interscapular region gives more definite results than percussion of the sternum. It also happens that in cases of pulmonary tuberculation, induration, characterised by dulness, takes its rise at the apex of the lung, and that the points at which the change in the pulmonary tissue is found are the superior clavicular or sterno-clavicular regions. When auscultation does not make the diagnosis clear, it is very difficult to decide whether we are dealing with a commencing tuberculous induration, or with a hypertrophy of the pretracheobronchial or retro-sternal glands. At the back the pleximetric phenomena are more often confirmed by the results obtained from auscultation. M. Gueneau de Mussy observes that, on daily examination of the chest of patients attacked by bronchial adenopathy, he finds modifications of the respiratory sounds, which are very important as means of diagnosis. They will vary according to the relation of the glandular tumours with the air-tubes, and according to the form and changes of form and size undergone by the latter. In slight cases expiration may be prolonged and slightly blowing (*soufflante*); when transmitted to the ear by the glandular tumour the

tracheal souffle is more easily perceived, and often takes on the character of a tubular inspiration. The voice and the cough will also exhibit an abnormal resonance. Indeed, after every fit of coughing another sound can be detected, which is called by M. Gueneau de Mussy the echo of the cough. At a later stage, the form and calibre of the air-tubes may be changed by the pressure they undergo, and they may become inflamed, when varying bruits will be perceptible. 'The tracheal and bronchial bruits,' says M. Gueneau de Mussy, 'are rough, sometimes rasping, and sharper than in the normal state; sometimes aspirated, giving a sensation of suction, which indicates the passage of the column of air through a narrowed channel. The expiratory sound is generally increased, and often overpowers the inspiratory sound; both sometimes end with a sibilus or a large bubbling râle, of which the constancy, the situation, and the persistence constitute, according to MM. Rilliet and Barthez, one of the most important signs of the disease.' The mobility of these râles is yet more characteristic, and specially also their peculiarity of echoing through a great extent of the respiratory system. But the most common and the most significant of all acoustic phenomena is the extreme weakness of the vascular murmur co-existing with the persistence of the pleximetric sonority, and showing itself through a large extent of lung. Many observers, and principally Stokes, Lebert, Hérard, Daga, Rilliet, Barthez, Noel Gueneau de Mussy, etc., have pointed it out and referred it to its true cause, the compression exerted on the bronchi by the hypertrophied glands. It has appeared to Dr. Lereboullet that, in pulmonary tuberculous with commencing adenopathy, this extreme feebleness of the respiratory bruit is often the only appreciable stethoscopic sign. At a later period functional symptoms add themselves to this character, and especially attacks of dyspnoea, which make its pathogenic interpretation very probable. Cruveilhier had already said, 'Many facts authorise me to admit, that the compression of the first division of the bronchi at the spot where they penetrate the thickness of the lung is not altogether foreign to the death by asphyxia of a certain number of children and tuberculous adults. We shall be certain of this if we carefully study the origin of the tuberculous lungs; and, if we follow the bronchial divisions into the thickness of the lungs to a certain depth, we shall see, independently of the large glands which surround the first division of the bronchi, smaller glands which penetrate into the thickness of the lungs with the secondary, tertiary, and quaternary divisions, whose angles of bifurcation they so thoroughly occupy that they flatten the tubes, and must render them scarcely permeable to the air. The attacks of suffocation undergone by some phthisical patients at an early stage of the disease may partly proceed from this cause.' A case cited by Dr. Jaccoud in his *Clinical Lectures* shows that this lesion of the intrapulmonary glands may exist without the hypertrophy of the glands which occupy the hilus of the lung or the bifurcation of the bronchi, being sufficiently pronounced to give rise to appreciable thermometric or pleximetric signs; but this cannot be the case in the majority of instances, and it can easily be understood that the weakness of the vesicular sound, as also attacks of dyspnoea, and finally asphyxia, may be the results of compression of the bronchi.

To sum up, then, interscapular or presternal dulness, a notable weakening of the respiratory

bruit with bronchial expiration, and increased reverberation of the voice and cough, are the most ordinary physical signs of bronchial adenopathy. M. Fonssagrives, and after him M. Baréty, also signalise the augmentation of thoracic vibration. Dr. Lereboullet has never observed it, nor the deformities produced by the projection of the glandular tumour, which have attracted the attention of several observers. On the contrary, he has seen the subclavicular or cervico-maxillary glands testify by their change to the lesion of the intrathoracic glands. A certain number of functional symptoms depending on the action exercised on the neighbouring organs by the bronchial glands serve to confirm the diagnosis, or even more frequently, by giving rise to suspicions of bronchial adenopathy, induce the physician to examine the superior thoracic region with more attention.

Dyspnœa is one of the most important of the symptoms. At first it is only a rather troublesome difficulty in breathing, only felt after some effort or a fatiguing walk; but soon this difficulty is almost constant, is accompanied by the most painful exacerbations, chiefly nocturnal, coming on in fits and being likely, as in MM. Fonssagrives, Gleize, and Durian's cases to end by asphyxia comparable to that brought on by strangulation. These attacks of dyspnœa, which are quite characteristic, have been differently interpreted. Sometimes, as in a case of adenoid, noted by Trousseau, they seem to have some connection with a compression exerted on the air-tubes. Cayol, Andral, Daga, Piorry, etc., have even quoted cases in which dorsal decubitus became impossible, the patients not being able to breathe except when leaning forward. The attacks of dyspnœa of a clearly intermittent character are, for the most part, related to neuro-paralytic phenomena due to the compression of the vagus nerve. They frequently appear to be dependent on the very rapid and extended pulmonary congestions which almost always accompany the development of tubercles, and which appear to commence with a rapid but transient increase in the size of the glands. Thus, after having lasted five or six days, showing themselves specially in the night time, these dyspnœal attacks often disappear for a fortnight, to re-appear on the occasion of a fresh crop of tubercles. Decubitus, and the hypostatic congestion, which it brings on; the accumulation of mucus in the small bronchial tubes (Hourmann); the fever always more marked in the night time; the vitiation of the atmosphere diminishing the amount of oxygen inspired, etc., all these causes combine, doubtless, to a certain degree, to augment the dyspnœa. In addition to the dyspnœa, a whistling inspiration, a broncho-tracheal wheezing (Empis), often perceived at a distance, and also a sinking in of the soft parts which enter into the composition of the walls of the thorax, a depression which is situated specially on the plane of the superior intercartilaginous spaces, and of the sub-sternal, subclavicular, and epigastric hollows, may be instanced as symptoms of the compression of the air-passages, thus constituting the phenomena of *tirage*. M. Gueneau de Mussy and, after him, M. Baréty, have also observed the diminution of the expansion of the thorax, which may be measured by M. Mathieu's pneumeter. The compression of the recurrent and pneumogastric nerves may bring on a series of somewhat interesting phenomena. The cough may be hoarse, dry, coming on in distressing and sometimes very painful paroxysms. M. Daga

compares it to the barking of a dog. M. Gueneau de Mussy has observed that it may take on all the characteristics of whooping-cough. In 1780 Lalouette, quoted by M. Baréty, had recognised this phenomenon in the following terms. 'It is while nature is labouring to deliver herself of a humour, which incommodes her, that congestions occur in the glands of the lungs and the mesentery, which, coming promptly to maturity, form suppurations destructive to infant life. The persistence of the cough changed into what is known as whooping-cough, the difficulty of breathing, the constant oppression, the redness and puffiness of the face, the small, rapid, and hard pulse, the slight shiverings, all announce suppuration in the lung, of which the glands are swollen.' M. Gueneau de Mussy explains those persistent coughs often met with, and difficult to cure, by adenopathy consecutive on whooping-cough. Like the cough and the dyspnœa already commented on, the changes in the voice equally depend on a compression of the recurrent and pneumogastric nerves. Dr. Lereboullet remarks that he has himself never yet met with anything but hoarseness of the voice and of the cough; and this symptom even was very transient, returning at certain periods, and of a varying duration. Aphonia has been noted in some cases, and even sudden aphonia with an attack of suffocation, in which the necropsy demonstrated the lesion of the recurrent nerve. MM. Gueneau de Mussy and Krishaber have proved that the laryngoscope can demonstrate paralysis of one of the vocal cords in these cases of aphonia. Finally, vomitings sometimes, but rarely, constitute the most striking and the most distressing phenomena of this disease. Like certain vomitings observed in phthisical patients, they appear due to an abnormal irritation of the pneumogastric nerve. If the phenomena which determine the compression of the trachea, the bronchi, or the pneumogastric nerves are of paramount importance, it is no less useful to know the symptoms observed when a venous stasis results from the compression of the vena cava superior. The very marked puffiness of the face, with the œdema of the eyelids, as symptoms of bronchial adenopathy, have been pointed out by a great number of writers, from Cayol and Piorry to Marchal de Calvi and Daga. This puffiness and œdema of the face appear to indicate a compression of the brachio-cephalic venous trunk, but they may sometimes depend on a momentary disturbance of the circulation which is altogether accidental. It is however, important to note that, when puffiness of the face is existent with the physical symptoms characterising bronchial adenopathy, it cannot by itself suffice to characterise the adenopathy. The same holds good of the other complications, such as venous dilatation, epistaxis, hæmoptysis, pulmonary œdema, etc., accidentally pointed out, and which appear connected with the pulmonary hyperæmiæ which often accompany the pulmonary affections which complicate hypertrophy of the bronchial glands.

Dyspnœa showing the characteristics already pointed out; the hoarse distressing cough, coming on in paroxysms, accompanied by a sero-spumous and sometimes sanguinolent sero-spumous expectoration; the changes in the voice; the crises of vomiting, the œdema and the puffiness of the face are in turn the functional symptoms which may most frequently be noted in cases of bronchial adeno-

pathy. But these symptoms are not sufficient to characterise it, and almost always the physical signs previously enumerated will allow its recognition. Bronchial adenopathy has been pointed out by M. Gueneau de Mussy in the course of small-pox, typhoid fever, and, above all, whooping-cough; but is it not common to find in these various diseases the complication with which we have now often met in cases of pulmonary tuberculation. At the commencement of tuberculosis, especially in children and soldiers, often the victims of tuberculosis of glands, adenopathy is very common. In patients debilitated by copious suppurations, especially when the suppuration is due to those caseous adenites of which the slow and progressive suppuration long arrests all treatment, chronic pulmonary congestion with bronchial adenopathy precedes the evolution of tuberculosis.

If looked after from the beginning, the pulmonary affection may be overcome; but if left to itself, pulmonary chronic congestion in common with adenopathy will soon be accompanied by circumscribed pleuritis with pulmonary sclerosis, speedily followed by the irremediable lesions which characterise chronic tuberculation. It is, therefore, important to advise methods of exploration which allow energetic treatment after the presence of the lesion is recognised. Frequent applications of tincture of iodine to the upper part of the chest; tincture of iodine in conjunction with croton-oil when the dulness extends to the anterior part of the thorax; tincture of iodine as a draught; arsenical preparations in large doses; narcotics, especially belladonna, for the cough; revulsives applied to the epigastric region or along the track of the pneumogastric nerves when vomitings or crises of dyspnoea come on, are the most efficacious therapeutic means.

SPINAL MENINGITIS TREATED BY CHLORAL.—

The *Archives Générales de Médecine*, for 1874, contains the record of a case of spinal meningitis, probably of rheumatismal nature, which was cured by the administration of chloral. The patient was a man aged thirty-seven, a currier, working almost constantly in water, but never having been troubled with rheumatism. He had been attacked three weeks before he came into the hospital with fever, accompanied by cephalalgia, anorexia, then with cramps in the calves of the legs and thighs, with pain in the posterior region of the neck, followed by permanent contraction of that region. When he was admitted into the hospital, on November 29, 1873, rigidity and contraction of the muscles of the posterior cervical region, pain at the level of the vertebral spinal apophyses, and a little want of sensation in the arms were present, as well as a contraction of the muscles of the thigh and leg, which imparted forced extension to the lower limbs, with complete anæsthesia extending from four inches below the femoro-tibial articulation to the ends of the toes. The muscles of the lower limbs were agitated by fibrillary contractions. The only cerebral symptoms were the diffused cephalalgia, which had been present for three weeks, and some sensations of confusion. There was no functional trouble of the rectum or of the bladder. The initiatory fever had disappeared. The pulse was 76, and the temperature was at 38.8° Cent. (101.84° Fahr.). All these symptoms disappeared towards March 1, after various remissions, and by March 20 the patient was completely cured. The contractions, the painful cramps, the anæsthesia with spontaneous pains, the absence of cerebral troubles, the immunity of the

bladder and the rectum, the absence of all paralytic or paretic manifestation, and the comparatively rapid cure, all made the diagnosis of spinal rheumatism admissible. The treatment employed certainly produced the best effects. Opium successively associated with sulphate of quinine, with tartar emetic, and with belladonna; then iodide of potassium in conjunction with belladonna, baths, dry and wet cupping, etc., only gave a very small amount of ease. Chloral only, administered for several days in progressively increasing doses, from three to nine grammes (45 to 135 grains) *per diem*, in divided doses was immediately followed by a very remarkable improvement, especially in relation to the tetanic symptoms. It is necessary in these cases to employ somewhat large doses, since it is demonstrated that narcotics or sedatives are only efficacious in convulsive affections of the spinal system, either clonic or tonic, when they almost approach the poisonous dose. In this case symptoms of intoxication only appeared late, and consisted merely of sleepy hebetude, a species of mild intoxication without excitement, hallucinations, dreams, without any change in the contractility of the pupil or any visual troubles.

LABOULBÈNE ON CYANOSIS.—At the meeting of the Paris Academy of Medicine, on December 18, M. Laboulbène communicated the details of a case of cyanosis which he had under his care at the Necker hospital. The patient was thirty years of age; his skin was of a dark colour, but his face was of a dark blue, especially in the middle portion, round the nose and lips, which were thickened. The neck was swollen, and showed venous pulsation, and the fingers were swollen into the shape of drumsticks. The disease had begun to show itself when the patient was about eight years old, but had made rapid progress during the last few months. At the present time examination showed signs of an organic affection of the heart, œdema of the lower extremities, ascites, and pulmonary congestion. The heart was hypertrophied and a noisy souffle occupied nearly the whole of the precordial region, attaining its maximum intensity at the level of the tricuspid and pulmonary orifices. M. Laboulbène believed that there was tricuspid insufficiency, and perhaps also constriction of the pulmonary artery; and that possibly also an abnormal communication existed between the right and left cavities.

SURGERY.

MOLLIÈRE ON TUMOURS OF THE TONGUE.—M. Mollière, surgeon to the Hôtel-Dieu at Lyons, makes the following observations upon some rare tumours of the tongue (*Progrès Médical*, no. 1, 1875).

Hydatid Cyst of the Tongue.—L. S., aged twenty-four, a schoolmaster, entered the Hôtel-Dieu, at Lyons, on Sept. 18 (?) 1874. This young man, who seemed to be of a robust constitution, dated his malady from the preceding March. A pimple then appeared upon the tongue, followed in a few days by violent pain. The pimple was then about the size of a pea, but rapidly increased. Inflammatory symptoms of great intensity supervened. The tongue acquired an enormous size, and for fifteen days the patient could swallow no food. When this inflam-

* There is evidently a mistake in the dates. Probably the 18th ought to be the 8th.—W. F. C.

mation ceased, he found the tumour of the same size as before. It was indolent, but it continued to enlarge, so that after some time he had much difficulty in performing the duties of his calling. When he entered the hospital a round and very hard tumour, about the size of a nut, was seen on the right border of the tongue, its greatest prominence being towards the upper surface. This tumour was well defined, regularly rounded, and indolent. The tongue was seized with a napkin, and drawn with a certain degree of force upwards and out of the mouth. It was thus rendered motionless, and in this way fluctuation was very distinctly observed. The tumour was diagnosed to be a cyst. On Sept. 12 it was operated on. The point of the tongue was seized with sharp forceps, and drawn outwards. A longitudinal incision was made in the dorsum, and the dissection carried on. The tumour adhered closely to the lingual tissues, and was deeply imbedded in the muscles among which it had its origin. There was also a deep adhesion to the ranine artery, which was opened quite at the base of the tongue. When the tumour was removed, it was very difficult to tie the artery. The wound was united by fine stitches of metallic suture. The patient was put to bed, and during the day was ordered gargles of iced and medicated water. Next day there was slight swelling. The tongue was as large as it had been before the operation, of a blue colour, and ecchymosed. There was no fever, and the temperature throughout the whole treatment never reached 39° Cent. (100.2° Fahr.) On the fourth day the stitches were removed. The clots which had accumulated were pressed out of the cavity, and on September 20 the patient left the hospital with only a small linear wound and slight swelling. He could speak freely, and had no pain. When the tumour was examined, a transparent vesicle with very thin walls was found within. It contained a small opaque point. This point was submitted to microscopic examination, and the parasite was discovered with its suckers and crown of hooklets, thus demonstrating the tumour to be an hydatid cyst of the tongue.

M. Mollière's reason for publishing this case is not so much the rarity of hydatid cysts of the tongue, for this rarity is only comparative; but because of the circumstances which accompanied it. The parasite must have entered the tongue during mastication, and the inflammatory symptoms were probably due to it. In the first place it acted as a foreign body, and we must suppose that the inflammation ceased when the parasitical cyst had formed. He calls attention particularly to the method he employed to demonstrate the fluctuation. Its value cannot be appreciated without a trial. It is, in fact, the only way in which the organ can be rendered motionless. The therapeutic treatment, also, he considers to have been the most certain and the most rational. Are we not certain by complete excision thoroughly to extirpate the evil? Total ablation also has the advantage of being much quicker than the other methods—injections, partial excisions, or cauterisations. Finally, he says, the only danger to be feared—that of hæmorrhage—is guarded against by the use of sutures. His observations upon this point are, in his opinion, as conclusive as possible, since the suture succeeded in arresting the flow of blood, even when it arose from a wound in the principal artery of the organ. It appears to him that the suture is not sufficiently used as a hæmostatic remedy in operations upon the

tongue. He speaks, however, only of the metallic suture. It has the immense advantage over sutures of vegetable material, that it covers the affected region with small sharp points, so that the patient instinctively keeps the tongue at rest.

Lipoma of the Tongue.—The patient was an old man, aged sixty. He had on the left side of his tongue a little tumour, of the size of a haricot bean. This tumour, which was seen under the stretched and transparent mucous membrane, was soft and of a yellow colour. The patient could give no information as to its origin or course. M. Mollière at first believed it to be an abscess or a syphilitic gumma. But there was nothing in the man's previous history to support this idea; and as the author could not discover any fluctuation, he concluded that it was a solid tumour, developed probably in the glands. As it continued to enlarge, he proposed its ablation, and proceeded as follows. A hole was made in a piece of cardboard through which the patient passed his tongue. An assistant held it, while the surgeon laid hold of the tumour with Guersant's hæmorrhoidal forceps, which had first been made red hot. After eight days the patient left the hospital cured. Histological examination proved that the tumour was a lipoma. Similar small tumours were seen at the base of the organ, but, as they caused no inconvenience, they were not touched. Lipoma of the tongue is very rare. M. Mollière calls special attention, however, to the method which he used in removing this tumour. It is expeditious, attended by but little pain, and is free from all danger of hæmorrhage. He says he has had recourse to it in other instances to remove small cancers situated on the point or edge of the tongue; and thinks that it ought to be substituted for the knife or the écraseur in all cases to which it is applicable.

W. FAIRLIE CLARKE.

MATERIA MEDICA AND THERAPEUTICS.

BROCHIN ON APO MORPHIA AND ITS PHYSIOLOGICAL AND THERAPEUTICAL PROPERTIES.—There has been much discussion for some time past respecting apomorphia and its physiological and therapeutic properties. Apomorphia, or rather the hydrochlorate of apomorphia, has chiefly an emetic action. It appears from many experiments made in the first instance in Germany and England, and more recently in France, that apomorphia produces vomiting, by what channel soever it reaches the organism, but that its effects are more prompt and more certain when it is introduced directly into the blood by intravenous or subcutaneous injection. If given by the mouth, the dose must be increased, and the effects are less certain. From the assemblage of facts known up to the present time, it would appear that apomorphia may be employed in subcutaneous injection without producing local accidents such as inflammation of the skin, consecutive abscesses, etc.; nor does the process seem to be very painful. The principal results obtained according to the reports of the medical men who have employed it, and who agree as to its principal points, are as follows. During the two or three minutes immediately following the injection, the patient does not feel anything. Soon a sensation of weight at the stomach, followed by a slight pain in the head, comes on. Then salivation becomes copious, the body is covered

with perspiration, one or two efforts at vomiting, without any result, occur, and at the third, or more rarely the fourth effort, the patient vomits three or four times successively; then comes a period of calm. The vomitings return after an interruption of five or six minutes, followed by another interval of calm, and the same scene is repeated five or six different times, to terminate definitively at the end of about half-an-hour, and to give place to a very quiet sleep, lasting from half-an-hour to an hour. Such, in brief, is the usual order of the effects produced by the hydrochlorate of apomorphia, according to M. Chouppé's paper on the subject, published in the *Gazette Hebdomadaire* for December, 1874, which contains all that is known on this new therapeutic agent.

The hydrochlorate of apomorphia has been injected in doses of from six to twelve milligrammes ($\frac{9}{10}$ to $1\frac{4}{5}$ grains), according to circumstances. Some experimentalists have fixed the dose at ten milligrammes ($1\frac{1}{2}$ grains) for an adult male, eight milligrammes ($1\frac{1}{5}$ grains) for a woman, and six milligrammes ($\frac{9}{10}$ grain) for a child. According to M. Chouppé, one centigramme ($1\frac{1}{2}$ grains) ought to be considered as the average dose for an adult. It must, however, be noted that a state of impending syncope, of such a nature as to cause grave apprehension, has already been observed in several patients. A case in point is reported in the *Gazette des Hôpitaux* of January 16, by Dr. Brochin, with the intention of warning practitioners against one of the possible dangers of this new drug. A woman, forty years old, went into the hospital at Geneva on October 22, complaining of gastric troubles without fever. After some days, she was attacked by sore throat and complete anorexia. The tonsils were red and swollen, and the tongue very much furred. A hypodermic injection of three or four milligrammes of hydrochlorate of apomorphia was administered to her in the sternal region. The pulse was full, and marked 100 beats. In four minutes the patient felt slight uneasiness and a little vertigo; she said she felt her head turning round and becoming stupid. She turned pale, became insensible, her pulse became extremely weak, intermittent, and then imperceptible; the pupils were dilated, and the respiration seemed to be entirely suspended. Slight tonic convulsions showed themselves in the left corner of the mouth and in the left cheek. The patient became inert, and did not answer to the questions addressed to her. When M. Prevost, under whose care she was, saw these alarming symptoms, he had recourse to every available means of exciting reflex action, such as sprinkling with cold water, inhalations of ammonia, energetic frictions, mustard-poultices, etc. The patient recovered consciousness in three minutes and vomited twice, after which she again fainted, became extremely pallid, and the pupils were alternately dilated and contracted. Counterirritation was again tried, and she was also electrified with an induction-current on the anterior portion of the chest. Improvement set in and gradually increased, until in about half an hour fresh vomitings followed by fainting again came on. Brandy and wine were given to the patient. In another ten minutes all danger seemed over, and she slept soundly for half an hour. She felt better when she woke, but up till twelve o'clock she continued to have sudden pallors, which did not, however, go so far as syncope. She, however, eventually recovered from the effects of the injection, and also from the gastric affection for which she had sought advice.

RAYMOND ON THE THERAPEUTIC ACTION OF BROMIDE OF CAMPHOR.—At the meeting of the Biological Society of Paris on December 26, M. Raymond communicated the details of two cases treated with bromide of camphor.

The first case was one of a girl aged nineteen, suffering from hysterical tremblings. Before she came into the hospital she was in a nervous condition, shown by a frequent desire to cry, pains in the epigastrium and back, etc. On the day of her admission she had a little gastric disturbance, and suffered from a dry, hoarse, spasmodic, hacking cough, recurring at irregular intervals, especially during the day. At the same time, she experienced difficulty in breathing, and some pain in the right side. Examination of the respiratory organs did not show anything abnormal. Twenty-seven days after her admission, when her general condition was satisfactory, after having for some days past complained of somewhat violent palpitations of the heart, she was suddenly taken in the morning with tremblings in the left leg, accompanied by the same symptoms, but less violent, in the right. The appearance of these tremblings was preceded by pains in the knees the preceding night. The trembling was specially restricted to the muscles of the thigh, and disappeared during rest. Sensibility to touch was absent in both the lower limbs. It was also accompanied with sudden movements always in the same direction. If the patient were desired to lift her leg, the muscles became the seat of convulsive jerks. The next day the shaking, which had on the previous day disappeared during rest, became persistent, and the right arm was affected. On the third day the left leg was agitated with involuntary movements, occupying nearly all the muscles; the leg was flexed over the thigh, and the patella was visibly raised during the contractions of the triceps. The movements were not so strong in the right leg. In the evening of this day there were tremblings of the tongue, palpitations, and a considerable amount of oppression. On the fifth day, treatment by bromide of camphor was commenced. The patient took five granules, and on the sixth day six granules. On the seventh day she was better; the tremblings were rather less violent, and sensibility reappeared in the members affected. On July 23, ten granules were given, and the movements had greatly diminished. On July 25, about 5 P.M., the patient was suddenly attacked with very powerful tremblings in the right arm and the left leg. On August 4, she took fifteen granules, and the trembling was improved. On August 10, she took nineteen granules, and the next day twenty. The improvement continued, and she soon left the hospital cured. In ten days she returned for fresh advice, as the tremblings had threatened to trouble her again; and she was again treated with bromide of camphor. She came back into the hospital towards the end of the month for some days, because the tremblings had returned, and again went out cured, after having again taken bromide of camphor.

In the second case, the condition was almost analogous; but is less conclusive, because the treatment by bromide of camphor was obliged to be interrupted, on account of the patient's complaints of suffering from gastralgia, which may possibly have been somewhat imaginary. She was a hysterical girl, aged eighteen, who, before her admission into hospital, had had four convulsive attacks without loss of consciousness. The last had occurred on the

eve of her admission. During the first month of her stay in the hospital, she had a mild attack of typhoid fever, from which she was not convalescent for some time. On her return from taking a sulphur vapour-bath, she was suddenly seized with tremblings of both arms and legs. The muscular jerks were regular, rapid, circumscribed, but rhythmical. The trembling persisted during rest, but disappeared during sleep. Sensibility remained intact. At the same time she had the characteristic oppression, globus hystericus, palpitations, and some spinal pains. Hysterical attacks and fresh tremblings of the right arm and left leg appeared. The patient was placed under treatment of bromide of camphor, commencing with two and then going on to ten granules. The use of the bromide of camphor was twice interrupted by attacks of gastralgia, and the cure was completed by bromide of potassium.

POLICHRONIE ON THE THERAPEUTIC AND PHYSIOLOGICAL ACTION OF IPECACUANHA AND ITS ALKALOID.—Dr. Polichronie (*Thèse de Paris*, 1874) has made a series of very interesting researches for the purpose of discovering the mode of action of ipecacuanha and of emetin. The clinical facts ascertained confirm M. Chouppé's results. M. Polichronie's conclusions are as follows. Emetin is the really active principle of ipecacuanha. All the physiological, therapeutic, and toxic properties of this plant are due to the presence of this alkaloid. Ipecacuanha administered in injections, in dysentery as well as in diarrhoea, possesses just as powerful properties as when it is administered by the mouth according to the Brazilian method. Injections of ipecacuanha form one of the best imaginable treatments for infantile cholera, and may be borne for a considerable time without weakening the little patients. In the diarrhoea of tuberculosis, injections of ipecacuanha give good results at all stages. This medication may also be advantageously employed to combat the profuse perspirations of phthisis. Emetin is a very toxic substance; it kills animals in two ways, sometimes by the prostration of the nervous system which it causes, sometimes, when given in small doses, by the intense enteritis which it brings on. Two hypotheses may explain the favourable action of ipecacuanha in diarrhoea; either a constrictor action on the vessels which would diminish the abundance of the secretions, or a substitutive action resulting from the inflammation of the mucous membrane. There is, however, no vaso-constrictor action, as demonstrated by the experiments made on the nerve of the submaxillary gland and on the arterial tension. The production of inflammation of the gastro-intestinal mucous membrane, and the length of time after which vomiting appears, seem, on the contrary, to plead in favour of the second hypothesis. Emetin brings on vomiting at the moment it eliminates itself by the gastric mucous membrane, as proved by the delay of the sickness and even more frequently its entire absence, after the section of the two vagus nerves; in this respect it acts quite differently from apomorphia and tartar emetic. These two substances, in fact, cause vomiting as quickly when the two nerves are cut as when they are intact. Finally, physiological and chemical researches into the action of this drug still more plead in favour of the elimination of the emetin by the gastro-intestinal mucous membrane. Emetin has no direct vomitive action on

the central nervous system, which is proved by direct injections of this substance into the cerebral arteries. It may, therefore, be admitted that in diarrhoea emetin acts by substituting a true inflammation leading to spontaneous cure for pathological inflammation; its effect under these conditions will be in all respects comparable to that of purgatives or of nitrate of silver. A vaso-motor action can no more be admitted in the perspirations, and we must believe either that by eliminating itself by the sudoriparous glands it tends to dry up their secretion, or that it acts by the revolution it produces in the digestive tube.

CARLES ON THE PURITY OF REDUCED IRON.—M. Carles (*Journal de Chimie et de Pharmacie*, 1874) has been making investigations into the composition and the value of preparations of reduced iron and pulverised iron employed in pharmacy. Iron was titrated by the acid of a solution of iodine in iodide of potassium, and sulphur, by absorbing the hydrosulphuric acid resulting from the action of the hydrochloric acid on the iron, in a solution of acid acetate of lead. The sulphuret of lead, when washed and dried, allowed the corresponding quantity of sulphuret of iron which had produced it, to be calculated by the help of its own weight. The residuum, insoluble in acid, was formed of carbon and silica. M. Carles has settled that all the reduced or pulverised irons not only contain oxide but sulphur, and sometimes even phosphorus and silica, which, when they are acted on by the acids of the stomach, give rise to very disagreeable eructations. Putting their purity out of the question, they also possess very variable physical characteristics. Certain specimens dissolve thoroughly by the cold process in hydrochloric acid diluted with its own volume of water, in two or three hours, whilst others resist the action of the same acid from eighteen to twenty hours. It is, therefore, perfectly justifiable to ask what can be the action of the liquids of the stomach on irons which resist hydrochloric acid for from eighteen to twenty hours, and if they do not almost wholly pass into the intestine as inert matter. The results of M. Carles's analyses are as follows:—

Iron.	Oxide of iron.	Sulphuret of iron.	Silica and carbon.
99,0	Traces.	Traces.	Traces.
75,0	24,0	Traces.	0,90
73,0	24,0	2,90	0,02
58,7	40,0	0,20	0,80
58,0	34,5	2,07	5,30
54,0*	45,0	0,40	0,40
52,0	46,5	0,20	1,10
32,0	55,2	1,20	11,59
70,0†	20,1	2,70	7,10

From his experiments, M. Carles comes to the conclusion that the reduced irons of commerce are defective as medicines, and that it is better to replace them by other soluble ferruginous preparations, which may be obtained in a pure state by all pharmacutists, which may be apportioned into exact doses, and of which the absorption is more certain.

MISCELLANY.

THE PHYSICAL AND MENTAL DEVELOPMENT OF WOMEN.—Dr. Gaillard Thomas, of New York, in his lately published *Practical Treatise on the Diseases of Women*, expresses his opinion that the human female, if placed under favourable conditions, should in physical and mental development be in no great degree inferior to the male; and he maintains that the customs of what is termed civilised life have depreciated her powers of endurance and capacity for resisting disease. Amongst the influences which, growing out of civilisation and refinement, tend to produce the diseases peculiar to the female system, Dr. Thomas enumerates neglect of out-door exercise, excessive development of the nervous system, and improprieties of dress. The author further observes that 'Neither appreciation of nor desire for physical excellence sufficiently exists among the refined women of our day. Our young women are too willing to be delicate, fragile, and incapable of endurance. They dread above all things the glow and hue of health, the rotundity and beauty of masculinity, the comely shape which the great masters gave to Venus de Medici and Venus de Milo. All these attributes are viewed as coarse and unladylike, and she is regarded as most to be envied whose complexion wears the livery of disease, whose muscular development is beyond the suspicion of *embonpoint*, and whose waist can be almost spanned by her own hands. These are they who furnish employment for the gynæcologist, and who fill our homes with invalids and sufferers.' These remarks are intended to apply to American women, who do not take as much exercise as their English sisters; but there is much in them which may be taken to heart by Englishwomen. There can be no doubt that active mental employment, healthy bodily exercise, and a simpler style of dress than that usually adopted by women and girls in the upper and middle classes of English society would materially conduce to the reduction of uterine and nervous diseases, and contribute to the ultimate health and well-being of the community at large, since 'Mothers of great men should themselves be great.'

MEDICAL EDUCATION OF WOMEN IN RUSSIA.—A correspondent of the *Times* gives an account of the arrangements for the medical education of women in Russia, which, it appears, are on a scale of magnitude of which little is known in this country. These arrangements are, we are informed, under the direction of a lady, and are carried on at the Academy of Medicine of St. Petersburg, in the same buildings and by the same professors as for the young men students, but at entirely different hours. Two hundred and forty young women have now been pursuing the course of training for three years, the term fixed being four. None have, therefore, at present been sent out to begin their work and profession. The payment is sixty roubles a year. A small proportion only come from the capital; the larger number of students are from the provinces, many being sent by the different governments or town councils, and their education paid for, on condition that they return to practise in these localities, where their services are eagerly anticipated, for in many of the distant parts of this vast empire medical aid is not to be had. There are three lady superintendents over the classes; the hours are from 8.30 to 4. The writer of these details bears witness that in the several classes which he visited where lectures were being given, the behaviour of the audience was all that could be wished as to earnest attention, intelli-

gence, interest, modesty, and seriousness; the extreme pains and evident interest shown by the professors being equally creditable and pleasant to behold. A large hospital is attached to and forms part of these vast buildings, so there is every opportunity of practical and theoretical instruction afforded on the spot. The writer also visited the cottage hospitals or 'barracks,' to which we have already drawn attention in these columns, and which have been opened during the last three years. They are pretty wooden chalets situated in a large space with trees, in an open and airy part of the city. Each house, or hall, contains sixteen beds, eight on each side, filled with men. The ventilation and warming arrangements seemed to be perfect, for the skylights above, and a lower floor beneath, for the apparatus for both purposes. A sister of charity superintends in each; but the chief point in this excellent scheme is the school for nurses attached to it, in which seventy young women are being trained, not only in the care of the sick, but in the higher branches of medical knowledge also; twenty pupils are resident, the others come by day. The entire nursing of these three hospitals is done by them, and the instruction is given by medical professors; students do not attend. There is a fourth hospital, for women, in a house close by, but the sanitary arrangements are found to be so far better in the wooden buildings that another is about to be constructed on the same plan, which will replace the house. The plan was begun after the war, and the red cross on the hospitals marks the connection with that period. Again, the writer speaks of being struck with the plain, sensible earnestness of the pupils, most of whom are orphans, who pay nothing, all the expenses being defrayed by the Empress. None have been yet sent out, but, as in the other case of the medical students, their services are eagerly expected and anticipated. The mortality in these hospitals is stated to be very low, and all the arrangements are of the most pleasant and comfortable nature.

ERRATUM.

In the review of 'Cholera: How to Prevent and Resist it,' in the MEDICAL RECORD of January 20, the word 'casual,' p. 43, column 2, line 18, should be 'causal.' The sentence should read: 'The mathematical probability that the connection [between variation of the ground-water and of cholera and typhoid] was causal, amounted to 36,000 to 1.'

NOTICE.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, FEBRUARY 3, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE FORMATION AND TRANSFORMATION OF BONE. BY PROFESSOR R. VIRCHOW.*

(Concluded from page 46.)

From these experiments it is inferred, rather too hastily in my opinion, that there is no possibility of the existence of another form of growth of bone, especially the so-called interstitial growth already described by Clopton Havers. I have taken the trouble, as Herr Wolff will admit, to take into account this eventuality also, and am convinced of the possibility of such interstitial growth. Herr Kölliker has, it seems, not taken sufficient notice of those experiments which I regard as very conclusive, namely, those of Herr Carl Ruge. Herr Ruge cut a piece from the bone of young animals, and determined the size of the bone-corpuscles and of the interspaces between them. He then, after waiting for some time, cut a similar piece from the corresponding bone on the other side. Having ascertained by previous comparison that the symmetrical pieces had similar relations to each other in respect of structure, he further found that in the piece last removed the interspaces between the bone-corpuscles had increased in size. The osseous corpuscles had become compressed, but had undergone little change in themselves. Herr Kölliker, so far as I understand him, has assumed that Herr Ruge re-examined the same piece after some time; but this is not the question. I regard this experiment as altogether satisfactory; and I can add that Herr Strelzoff has arrived at similar results.

But, admitting that there is interstitial growth, it is still placed beyond doubt by the measurements of Herr Ruge, that the results of this growth are relatively small. Although the differences in the distance between any two bone-corpuscles are capable of measurement, the total result is yet very small, and does not go far towards the lengthening of an extremity or of a tubular bone. Only a fraction of the material which contributes to the construction of the body arises in this way; but so long as these researches are not refuted, so long as no judgment is pronounced against them, so long must I maintain that they are worthy of regard.

The peculiarity of certain parts has to be here considered. A long time ago, I pointed out that the lower jaw was an object specially fitted for these discussions; and a number of experiments have been made on it, but no general agreement has, as yet, been arrived at. Thus, Herr Kölliker has declared himself in favour of growths by apposition; Herr Strelzoff in favour of interstitial growth. While I am still of opinion that the jaw affords

grounds for supposing that interstitial growth takes place, I must at the same time call special attention to the fact that there are few bones in the human body which present the same conditions as the lower jaw.

The formation of the teeth is something exceptional; but even in itself the lower jaw possesses much that is special. In the examination of its mode of growth, the attention of observers has diverged in very different directions. All, however, even Herr Kölliker, have acknowledged that the middle piece, which supports the incisor and canine teeth, enlarges much more than would be expected according to the *à priori* ideas on the possibility of this growth from the original cartilage at the symphysis. Very early after birth, the union of the symphysis is already so complete, that new materials for growth outwards can no longer be furnished from this part. Nevertheless, the individual parts diverge from the middle line, the places of the individual teeth are pushed farther back, the foramina mentalia become more and more apart from one another. The explanations that have been given are not sufficient to account for the growth of these parts by the apposition and resorption theory alone. According to this theory, the lower jaw should grow chiefly at its posterior end. It is certainly capable of proof, that absorption takes place at the anterior margin of the coronoid process of the condyle; giant-cells lie here and eat away the bone. As at the same time there is apposition from without at the posterior part of these processes and at the angle of the jaw, the possibility certainly arises that the ramus of the jaw grows in a direction backwards. Besides this, it is assumed that apposition and absorption take place on the alveoli, in such a way that there is apposition on the median surfaces, absorption of the external (posterior) ones; so that the whole row of teeth gradually moves backwards (outwards). But here there arises a great difficulty. Such a movement is readily understood; but it is not yet proved. Moreover, it has its own exceptional difficulties to overcome; for the teeth pass out of the alveoli in the direction of the nerves and vessels which enter their roots and lie in special canals. This is a difficulty which is not yet solved, and which rather affords an argument in favour of a certain interstitial formation. Nevertheless, I will accept another theory if it can be proved. I only assert that in the mean time no one has a right to say that these facts are irrelevant, and that they are capable of a quite simple interpretation by the recognised method. If, moreover, we take into comparison the opposite conditions, such as are met with after the loss of the teeth, and in old age, that is, the descending series, it is difficult to avoid admitting that here interstitial atrophy is added to the indubitable and powerful process of external absorption which takes place.

I will, as the time is advanced, allow myself only a few remarks with reference to the spongy substance. One is, as to the disposition of this substance; I find that here there is still more difficulty as to terminology, since, as far as I can make out, the name spongy substance has been applied to two different things. When young, bone is formed in a certain degree of abundance, as is especially the case in pathological cases, *e.g.*, in many forms of periostitis, it usually shows a looser and very porous structure, and an opaque whitish colour. In pathological language we rightly call this an osteophyte. In quite thick

* Read before the Berlin Medical Society, November 25, 1874. (*Berliner Klinische Wochenschrift*, January 4 and 11.)

layers, it sometimes assumes the consistence of pumice-stone. If the tissue be examined microscopically, spaces are seen, which are surrounded by osseous tissue, and filled with a softer tissue, a kind of marrow. But this is not proper spongy substance; it is what Guérin, in the history of rachitic bones, has distinguished as spongioid. If it remain persistent, it is converted on the surface of the bone into compact substance. Provisional callus also, the first stage of the formation of callus, depends on the presence of a mass of this kind; and no where can it be better seen than that it first becomes compact, and that only at a later date and under certain circumstances does it pass into spongy matter. Here is a very old preparation of a lower jaw that has suffered from phosphorus-periostitis, where the bone is covered externally with quite thick layers of osteophyte. I have brought the preparation with me, because the jaw was necrosed and thrown off after the formation of the osteophyte, and because it was the first case in which I was able to observe a complete regeneration of the bone from the periosteum. It is now twenty-five years since I brought the case forward at the jubilee meeting of the Würzburg Medical Society.

In the majority of cases these deposits are very thin, quite fine, not only in the normal growth of bone from periosteum, but also in periostitis. I pass from these matters, as they are generally known. Less known, however, are the great secondary osteoporoses, which are sometimes developed in supracortical layers outside the compact substance of the bone. Thus there is a *supracortical spongy substance*. Our collection possesses excellent specimens of this rare condition, which Lobstein has called *osteopsathyrosis*.

Diametrically opposed to this condition is the new formation of spongy matter in the medullary cavity, in places where otherwise no osseous tissue is formed. Under pathological conditions there is sometimes here a reproduction of spongy bone, as dense as is met with at the ends of the bones. Here you have a case of a thigh-bone, with metastatic cancer of the medullary cavity, in which, not in the cancerous deposits, but very extensively around them, the whole medullary cavity is filled with spongy substance. This is central spongiosis.

I now end my communication, the special object of which was to demonstrate by examples the great mutability of the inner formation of bone. There is indeed a great agreement from childhood to adult age in the disposition of the lamellæ of spongy tissue in normal bones; but the same uniformity by no means exists in their number. Herr Wolff has rightly insisted on the great constancy of duration which certain lamellæ show, although they constantly undergo lengthening. Hence he concludes that these lamellæ grow in length by interstitial deposit and not by apposition. Yet it may be proved in the most conclusive manner, that the number of lamellæ of the spongy tissue is not the same at different periods of life. Every one must agree with me that this can only be explained by the formation of new lamellæ, which thrust themselves between the old ones, or by the entire destruction of the old lamellæ, and their replacement by new ones. The accommodation of bone to various conditions is so great, that it has for centuries demanded the attention of investigators; and yet there are still peculiarities which have hitherto been explained not at all, or only with great difficulty. I may, for instance, remind you of

the property which every bone has of forming new cortical substance. As an example, I lay before you some amputation-stumps, where you can see the formation of this secondary cortical substance at the end of the medullary cavity. This is a phenomenon of which we have no settled interpretation. For the teleological explanation, that the bone protects itself by means of the new cortical substance against injury of its soft parts, is nothing but a circumlocution of the fact. It is somewhat different with the researches on the architecture of the spongy substance. The service which all such researches have rendered in fixing attention on the mechanical conditions of the internal structure of bone, in adducing proof that the arrangement of the spongy matter is not accidental, but that it must be such as serves the mechanical objects of bone, and that it is regulated by certain mathematical principles—this great service will remain permanent. But the bone-builders (*Knochen-Architekten*) must learn to understand that the idea is untenable that the lamellæ, when once formed, are fixed parts of the bone, which neither can nor dare be changed. They must arrive at the conclusion that not only does new marrow proceed from compact cortical bone, but that also new lamellæ are formed from medullary tissue, and that the place, duration, and thickness of the new lamellæ of the spongy substance is regulated by the special local conditions. I hope that in the end even our opponents will become convinced that this view is better than the assumption of a predestinated constancy and duration of the internal arrangement of bone, for it shows us the way in which we have to seek for the explanation not only of the usual, but also of the unusual dispositions of the minute parts of bone. This way, which now appears fixed, will certainly be lastingly fortunate; and I have no doubt that in following it we shall arrive at an explanation of the fact that in certain places, and under certain conditions, the marrow again becomes ossified and forms new bone.

ON ALCOHOL. By B. W. RICHARDSON,
M.D., F.R.S.*

The Position of Alcohol as a Food; its Effects on the Animal Temperature; Hygienic Considerations.

The question that lies before us for discussion to-night is short and definite. It is included in the three words: Is alcohol food?

We have studied in the previous lecture the purely physical action of alcohol on the animal body, that which stands apart from the action of food, and we have learned from the study that over the nervous system and over the vascular supply this spirit exerts a specific influence. We now inquire whether the influence ends there, or whether there may be, in addition, either a sustaining, and constructing, or a heat-giving power—that is to say, a force-giving quality in it. If there be, then the simple physical effects are perchance tolerable, or at all events are not sufficient to militate against the advantages which lie on the food side of the question.

It may be well to rest for a moment to consider the position of men and animals upon the earth in relation to the means given to them for their support as living, moving, and, in the higher animals, thinking structures. This position is well defined. The theory that man was made originally out of the dust

* Cantor Lecture, No. IV. *Journal of the Society of Arts.*

of the earth is, after all, the most scientific theory that has ever been advanced as to his primeval origin, if the word dust be only extended so as to include the actual compound substance of the earth. For in the earth are to be found not only all the elements out of which he is constructed, but even certain of the elements in the same kind of combination as we find them in him. In the earth, water, salts, and organic matter are found; in man the same are found. The man is in many respects of motion a reflex of the motion of the earth, presenting periodicities of movements, and of movements in a circle in like mode. As if to complete the analogy, this remains true, that the earth yields spontaneously to man, either from herself directly or from the vegetable kingdom which lies between her and man, all the requirements for his existence. Whatever, therefore, man invents, though it may seem to be a great necessity, is not a necessity except to those who, being trained to its use, have been led artificially to believe it essential. Thus nature has produced water and milk for man to drink, and they are, in truth, all the fluids that are essential. This lesson, which nature teaches by her rule of provision for the necessities of animal life, is supplemented by many other facts, each equally authoritative. There is ever before us the great experiment that all classes of living beings beneath man require as drink none other fluids except those I have named. We see the most useful of these animals performing laborious tasks, undergoing extremes of fatigue, bearing vicissitudes of heat and of cold, and enduring work, fatigue, and vicissitudes for long series of years, sustained by their solid food, with no other fluid than simple water. We see again whole nations and races of men who labour hard, endure fatigue and exposure, and who live to the end of a long and healthy life, taking with their solid sustenance water only as a beverage.

When we turn to the physiological construction either of man or of a lower animal, we discover nothing that can lead us to conceive the necessity for any other fluid than that which nature has supplied. The mass of the blood is composed of water, the mass of the nervous system is composed of water, the mass of all the active vital organs is made up of the same fluid; the secretions are watery fluids, and if in any of these parts any other agent than water should replace it, the result is instant disturbance of function that is injurious in proportion to the displacement.

When we turn therefore to the use of such a fluid as alcohol under any of its disguises,—as spirit, as wine, as beer, as cider, as perry, as liqueur,—we are driven *à priori* to look upon it as something super-added to the necessities of life; to look upon it, in a word, as a luxury. In such sense it has always been received amongst those nations which have most indulged in it. It is something added to the ordinary life, something unnecessary, but agreeable. Wine, added to the meal, transforms the meal into a feast; it is supposed to make glad the heart, but it is never supposed that if the wine were not possessed the life would be shortened. When now we offer wine, it is by the effect of habit and education, an offering of a thing that is super-necessitous, and in such wise a compliment, an indication of desire or of willingness to be exceedingly hospitable.

All the evidence of a general kind which can be gathered from these observations points to the use-

lessness, for man, of so artificial an agent as alcohol. But, after all, an assumption so derived may be false. We have already seen that when alcoholic spirit is taken into the animal body it produces in it exceedingly marked effects; it may therefore, by accident, I might almost say, play in some manner the part of a food and supplement water. Indeed, it is a form of water in which a compound of carbon and hydrogen has replaced hydrogen. Let us then ask the question: Can alcohol be in any sense accepted as performing any other part in the body save that physical part which we have considered? Can it have happened that man, by his invention, has added, to nature, a food? And let us answer the question as candidly as the facts of experiment and experience will permit.

Constructive Materials of the Body.—The living animal body is constructed out of a few simple forms of matter, which possess, during life, the power of motion. It is, in its living state, a noun and a verb. Whatever helps to maintain it in perfect order of construction, whatever enables it to move of its own mere will and motions, may be considered as a food. The one help gives matter and mass, the other gives force or spirit to the mass. With the progress of organic chemistry, after the discovery of the art of organic analysis, it soon became evident that what are called foods are divisible into two great classes; those which supply material or tissue, and those which supply heat or other variety of force. Gradually it was detected that the building foods all contain the element nitrogen as an essential part, and that the force-supplying foods are free of nitrogen, are hydrocarbons, substances that will undergo combustion by oxidation, and thus liberate force for the motive uses of the economy. So foods have for a long time been sharply classified as nitrogenous or tissue-feeding, and as respiratory or heat-producing. At the present moment this long-accepted view is undergoing some modification. It is being elicited that the nitrogenous foods are to a certain degree heat-producing, but I need not at this stage enter on the nice question involved. I may safely, for the practical purpose we have in view, let the division of the classes of foods remain as described above.

The nitrogenous foods exist in the animal body in the form of what is called colloidal matter, the word colloidal being a term signifying a jelly-like substance. The purest form of this matter is found in the blood in the white, elastic, plastic matter, called fibrine. By repeated washings of a portion of this substance I have prepared here, from the blood of the ox, a beautiful specimen of this colloid of the blood. Of a similar colloidal substance, the moving muscles are formed. In a fluid state, and permanently fluid at the temperature of the living body, the colloid called albumen forms part of organic structure. Under the names of gelatine and chondrine, a nitrogenous colloidal substance forms the organic matter of the skeleton, of the cartilages, of the sheaths of muscles, of the tendons. The eye-ball is constructed out of a series of colloidal tissues. All the membranes which envelope the visceral organs, and which possess elasticity, are colloidal. The outer covering or skin is colloidal, the nails are the same. Even in the brain and nervous matter there is distributed a colloid. Thus, if we sum up the various parts of the body we may say that all the active masses of structure are nitrogenous and colloidal.

In combination with this active matter, there are, however, two other material ingredients, viz., water and saline substance. Upon its combination with water, the activity of the colloid depends. Upon the saline rests the various kinds of combination of the colloid with the water. In bone the gelatine is combined with a salt, called phosphate of lime, with carbonate of lime, and other salts, in much larger proportion than itself. In fibrine the colloidal substance is nearly divested of saline; but in all parts these three material compounds make up the animal structures.

Lying outside these structures in the natural state, but really as an adventitious formation, is one other animal product, viz., fat; a substance detrimental to the motion of the active parts when present in excess, but at the same time capable of combustion, and of yielding heat by the process.

We have now before us the constructive or building parts of the animal body. Excepting the water, the salts, and the fat, they all contain nitrogen, and they take their specific quality from that specific fact. We know that the source of them is the vegetable kingdom, that they are formed by nature in that kingdom, are transferred from the vegetable to the animal, are not made by any natural process within the animal, have not yet been made by any artificial process known to the chemist, and can therefore only be supplied from the one natural supply.

Alcohol contains no nitrogen, it has none of the qualities of these structure-building foods; it is incapable of being transformed into any of them; it is therefore not a food in the sense of its being a constructive agent in the building up of the body.

In respect to this view there is, I believe, now no difference of opinion amongst those who have most carefully observed the action of alcohol. There is, however, a difference in relation to its action as a fat-forming food. It appears to be on evidence that men and animals beginning, while in a perfect state of health, to take in excess certain fluids containing alcohol become fattened. Notoriously, ale and beer fatten; and in some parts of the country certain animals—calves for instance—are rapidly fattened by the process of feeding them with a mixture of barley flour and gin. But through all these apparent evidences there may run an error. The fattening may not be due to the alcohol itself, but to the sugar or the starchy material that is taken with it. As a matter of general experience on which I have tried to arrive at the truth with as much accuracy as can be obtained, I am led to the conclusion that pure spirit drinkers among men, I mean those who do not mix sugar with the spirit, and who dislike spirit which is artificially sweetened, are not fattened by the spirit they take. This tallies also with the observations on the action of absolute alcohol on inferior animals, for they certainly, under that influence, if they are allowed liberty to move freely, do not fatten.

The question of the effect of alcohol in fattening presents still another difficulty. Alcohol, when it is largely taken, unless the will of the imbibor be very powerful, is wont to induce desire for undue sleep, or at least desire for physical repose. Under such conditions there is an interference with the ordinary nutritive processes. The wasted products of nutrition are imperfectly eliminated, the respiration becomes slower and less effective, and there is set up a series of changes leading, independently of the alcohol as a direct producer of fat, to development and to deposit of fatty tissue in the body. All these

circumstances militate against the hypothesis of the origin of fatty material direct from alcohol, nor is there any obvious chemical fact that supports the hypothesis. We understand chemically the transformation of starchy matter into one form of sugar, and we infer that in the animal body sugar is transmutable into fat. We know also that we can transmute sugar into alcohol, but as yet we see no way back from alcohol into sugar; if we did, the difficulty of tracing alcohol into fat would probably be over.

Physiological argument nevertheless lends some countenance to the view that alcohol may, by an unknown process, be transferable into fat. It is true that some confirmed alcoholics who do not wax fat in the ordinary sense of the term, that is to say, who do not fill out with fat, from the separation of fatty matter in their cellular tissue outside the vital organs, do, in certain instances, undergo a process of fatty change within their organic structures. Their muscles, including the heart, become the centres of the degeneration called 'fatty,' and by the interposition of cells of fat in the minute muscular elements, the activity of the fabric is destroyed, sometimes to a fatal destruction. The same degenerative change may extend also to other organs, to the brain, and to such active glands as the liver and the kidney.

At first view it occurs to the mind that here is evidence of effect upon cause. At the same time it is not so clear that the effect is direct from the cause; for when we proceed to examine into all the data that lie before us, we discover such an absence of uniformity in differing examples of the fatty change that we lose alcohol as the clue to discovery. Some alcoholics truly present the fatty modification of tissue, other alcoholics do not present it, so that alcohol may be in active operation and may neither be promoting the production of fat from other material nor yielding it. Lastly, the fatty change of tissue may progress, in the absence of alcohol, in the tissues of those who altogether abstain.

In conclusion, therefore, on this one point of alcohol, its use as a builder of the substantial parts of the animal organism, I fear I must give up all hope of affirmative proof. It does not certainly help to build up the active nitrogenous structures. It probably does not produce fatty matter except by an indirect and injurious interference with the natural processes.

If alcohol be not a substance out of which the animal tissues are formed, may it not be a source of energy of actual motion; may it not supply the power of doing work? Alcohol, we see, contains two elements that will burn in the presence of oxygen, viz., carbon and hydrogen, and although by their combination already with oxygen in the alcohol, a certain measure of their potential energy is lost, they are still capable of combining with more oxygen. This is proved by various experiments. When alcohol is burned, that is to say, when, with its combustible elements, free oxygen combines, there results from the chemical combination a certain degree of heat. The heat produced does not approach that obtained by an equal weight of hydrogen, it is not so great as that produced by an equal weight of carbon, but it is greater than that caused by the combustion of phosphorus, and very much greater than that caused by the combustion of sulphur.

The combustion of alcohol thus spoken of is that active combustion which is excited when a light is brought into contact with it so that its vapour may burn. But it is not actually necessary that such

instant active combustion should be set up. If we distribute alcohol over a wide surface in the presence of some chemical substances it will then by its combination with oxygen liberate a greater or lesser degree of heat. If I saturate a portion of paper with alcohol and on that paper pour a little of this finely divided powder, called platinum black, I at once get evidence of heat which may be so active that perfect combustion may ensue. In this instance the alcohol is transformed, as in burning, in great part, nay it may be altogether, into carbonic acid and water, which means the completed combustion. If in place of absolute alcohol, in this experiment, I use alcohol diluted with water, then instead of obtaining the active combination and combustion I get a slower oxidation with the production of substances to which attention has already been directed, viz., aldehyde, acetic acid, and volatile acetic ether. In this jar I have in progress these various changes in alcohol produced by the mere exposure of the vapour of alcohol to platinum black damped with water, in the presence of the air.

(To be continued.)

MURRI ON THE THEORY OF FEVER.*

The fact that dogs with divided cervical spinal cord cool more rapidly in cold air than healthy dogs, whilst in warm air they become warmer than the latter, led Naunyn, Quincke, and Von Dubczanski to the supposition that, after section of the cervical spinal cord, the amount of heat given off in consequence of paralysis of the vessels is increased, and simultaneously, the amount of heat produced is increased, and this latter, by the removal of influences inhibitory of the production of heat—these inhibitory influences proceeding from the brain. Substances which produce fever were said to act in a similar way. It is questionable, however, as Riegel has already pointed out, whether dogs with divided spinal cord have not much more lost the capability of giving off more heat in a warm atmosphere. This view is favoured by the absence of the so-called heat-dyspnoea and of the influence which heat exercises on the pulse and the blood-circulation in animals not operated on. It has been generally assumed, without any estimation, that the dogs operated on give off more heat in cool air than the healthy ones. Murri shows that the reverse must be the case; if, for instance, in a comparatively small part of the body (*e.g.* on one ear) there arise vasomotor paralysis, then this part, through increased supply of blood, becomes warmer; when, however, *all* the vessels of the body have been paralysed, it is not obvious how, upon the whole periphery, an increase of blood-supply and giving off of heat should arise. The diminution in the blood-pressure must on the contrary lessen the quantity of blood flowing through the capillaries in the unit of time, and thereby the radiation of heat. In addition to this, the absolute quiescence of the muscles in consequence of paralysis leads to venous stasis, and so a part of the blood is removed from the circulation.

From the experiments of Goltz and Naumann upon the influence of vascular tonus on the circulation, it equally follows that section of the spinal cord must greatly injure the circulation; the simultaneous

paralysis of the splanchnic nerves permits of the greater part of the blood to accumulate in the abdominal vessels. As a clinical proof that interruption of the spinal cord retards the circulation, the author cites a case of sudden circumscribed compression of the spinal cord in consequence of the penetration of pus; in this case oedema occurred in the paralysed lower half of the body, without, either at the bedside or at the necropsy, there being found any disease of other organs, or any circumstance other than disturbance of the circulation. The experiments of Murri, made upon dogs, show in fact that after section of the cord the skin is less warm, and gives off less heat than normally. Simultaneously with measurement of the rectal temperature, the temperature of the skin was taken with mercurial thermometers, which were either bound to the skin, or (generally) introduced through a wound, under the skin. The temperature of the skin sank after the operation in large as well as in small dogs, in a cool atmosphere as well as by a temperature of 30° Cent. (86° Fahr.). On increasing the temperature of the air, in the course of an experiment, to 40.2° Cent. (104.36° Fahr.), the temperature of the skin rose only to its original value of 39.6° Cent. (103.3° Fahr.), whilst that of the rectum rose to 41.6° Cent. (106.88° Fahr.) against 40.4° Cent. (104.7° Fahr.) before the operation). Cooling of the skin also took place, when, the temperature of the room being about 25° Cent. (77° Fahr.), the internal temperature rose after the operation. And when, in course of the experiment, the temperature in the rectum had risen above the normal, in spite of regular, frequent, repeated measurements, the skin was never observed to become warmer. It is not to be thought of that the skin, always cooler than normal, should give off greater quantities of heat than normally; it must give off less. The direct measurements of the heat given before and after section of the cord, were carried out in the following way. The dogs were placed in a wooden box, at a constant temperature of the room of 24° Cent.; the increase in the temperature which the air in the box underwent, at distinct intervals of time, through the presence of the dog, formed the measure for the amount of heat given off by the animal. It was shown that the dogs warmed the air of the box much more before the operation than after it. Now, in spite of the diminished giving off of heat, the interior of the animals became colder; they must therefore have produced less heat after the operation. Further, this diminution of production can be explained by the paralysis of the muscles, by the disturbance of the circulation which leads to imperfect supply of oxygen to the organism, farther from the diminished muscular work of the heart, and by the diminution of the internal friction of the blood-current, etc. Now, in opposition hereto, in fever more heat is produced than normally under the same conditions; the result of section of the spinal cord cannot therefore be applied to the theory of fever. Inasmuch as, further, no experimental lesion of the nervous system is known, which by itself increases the production of heat in the tissues, the theory of the neuroparalytic nature of fever falls. And even if septic fever actually had this origin, the generalisation for all fevers is not established.

Murri further divided the cervical spinal cord of dogs, in which he had produced septic fever; here the operation had not the above-mentioned cooling influence.

In other experiments the author divided, first the

* A. Murri, Sulla Teoria della Febbre. Fermo, 1874, 8vo, 132 pp. From Abstract in *Centralblatt für die Medicin. Wissensch.* no. 1, 1875.

cord (which produced a cooling) and then injected foetid pus under the skin of the dogs, on which their temperature rose quite as in the animals not operated on. These operations, whereby the hypothetical 'heat-inhibiting centre' in the brain is excluded, speak against the supposition of Quincke and Naunyn, according to whom pyrogenic substances produce an increase of temperature by paralysing the heat-producing inhibitory centre lying in the brain. On the contrary, they are easily explained from the point of view of the bio-chemical theory of fever (according to which pyrogenic substances, equally with ferments, produce abnormal chemical decompositions—a theory which is supported by Murri.) Septic fever can be produced even after destruction of the whole lower section of the spinal cord. The observation of Sapalski, confirmed by Von Dubczanski and Naunyn, that feverish animals, in a cool atmosphere cool more rapidly than sound ones, Murri cannot thoroughly corroborate from analogous experiments performed in a somewhat modified form on rabbits only. Sometimes the feverish (septic) animals cool more, sometimes the sound ones. However, allowing this analogy between feverish animals and animals with divided spinal cord, still this analogy is no identity, for then, also, the winter-sleep, which this analogy shows, would also be identical with 'fever.' Further, clinical observation shows, that patients do not in all feverish diseases cool more rapidly than healthy individuals.

Senator (and Heidenhain) consider that in fever the cutaneous arteries are more excitable than normally, and by frequent contractions limit the amount of heat given off. The author believes that he can refute, from observations on typhoid and pneumonia, this supposition, where continually and for a long time an equally warm skin is to be found (although Senator himself had shown that in spite of a hot skin the arteries do not require to be widened *ad maximum*, and can even be narrowed, Filehne). In a patient with pneumonia, Murri measured the temperature under the toes; it remained for hours constant, 37·8° to 37·9° Cent. (100·04° to 100·22° Fahr.), with an axillary temperature of 40·5° to 40·6° Cent. (104·9° to 105·08° Fahr.). The relation of these numbers is quite the same as exists in health.

Murri further questions the difference between feverish and healthy individuals which Senator proposed, viz., that the regulation of heat is insufficient. The muscular work of a healthy person lasts only a limited time, and during the pause the body first rids itself of the surplus heat; if here the heat-forming process (muscular exercise) were constantly continued, then the healthy individual would also no longer be able to regulate it. The febrile process goes on without a break, and it is not proved that the fever-patient would not regulate his condition of heat quite as quickly as a sound person, if the feverish excess of production gave him the necessary pauses. The above-cited experiment of Sapalski, together with Senator's view, that his feverish dogs cooled considerably in cool calorimeters, support the view that in septic fever the capability of giving up heat is not diminished, or that this view is quite a secondary matter for the theory, and appears to the author to prove that the higher temperature is chiefly dependent simply upon the increased production. Murri does not, however, question the reliability of Senator's deduction for all cases.

Murri further shows how all clinical processes (incubation, predisposition, immunity, spontaneous

origin, etc.) are throughout explicable with the light of the bio-chemical fever theory, whilst from the neuro-paralytic point of view they are quite inexplicable. The latter also does not explain the qualitative metamorphic changes in fever.

The author then enlarges upon his views of fever (already fully explained in the LONDON MEDICAL RECORD, November 26, 1873), and replies to Hüter, who had made as the outset of his theory a single observation on frogs, although he had not proved in his frogs the essential phenomena of fever, e.g. increased heat, whilst notwithstanding these animals, as former investigations have shown, have a temperature which is slightly higher than their surroundings, i.e. show a proper production of heat. In addition, this or that phenomena might be present in a certain fever (septic) and absent in another kind, so that 'globulöse Stase,' as such, does not belong to fever. Murri regards Hüter's theory as refuted.

The antipyretics the author divides into antipyretics (properly so called) and refrigerants. The former act directly against the perverted bio-chemical process (like quinine in ague) either by annihilating the exciter of the disease, or by so changing the organism that the conditions for the existence of the exciter of the disease are no longer present: the refrigerants (as digitalis in small doses) only afford favourable conditions on the part of the circulation, etc., for the giving off of heat.

WM. STIRLING, D.Sc., M.B., Edinburgh.

FÉRÉOL, RINGER, GOULD, AND TWEEDY, ON JABORANDI.

Dr. Féréol contributes, to the *Journal de Thérapeutique*, details of his experience in the administration of jaborandi to eight patients in his wards, at the Maison Municipale de Santé. The results obtained are so much the more remarkable, that Dr. Féréol always administered the infusion in cold water, and, as a rule, only gave one-half of the dose usually considered efficacious; that is to say, only two grammes of the leaves. Nevertheless, not only was a true salivary flux produced, but in some patients a diaphoresis, in some instances excessive. Dr. Féréol informs us that this result can be produced fifteen times, in succession, during six weeks, without any untoward consequences. He gave the jaborandi to eight patients, who furnished twenty-eight trials. Three patients submitted to its influence once only; two of them because they felt sickness going on to vomiting; and the other, a rheumatic patient, because he had a cardiac affection. Amongst the five others, one man took the jaborandi fifteen times in six weeks, at intervals of one, two, five, and six days. He was not at all distressed by it, and would willingly have persevered in taking it longer. The other patients were experimented on twice or thrice. The drug was administered as a cold infusion, in the proportion of two to four grammes of jaborandi to 250 of water. It caused nausea or vomiting in two cases only. In one of these cases, Dr. Féréol was convinced that the patient had, contrary to directions, taken food very shortly before drinking his infusion. The other case remained doubtful. The jaborandi never failed to produce copious salivation, even in patients who had only taken a small dose of it, or even in those who had vomited or only felt nausea. Its action on the perspiration was less constant and less powerful. In one case it was *nil*; in another slight; moderate in three cases; and

only really powerful in four. In one of the last category it was extremely copious, and the phenomena could be reproduced. This double action appeared from ten minutes to half an hour after the jaborandi had been taken, and lasted from one to two hours.

The influence on the pituitary membrane was three noted. The mucous membrane of the eye only appeared to be affected in one instance, and that in a doubtful manner. The examination of the urine was not altogether satisfactory; it was only carried out in five experiments on two patients; in one of them, suffering from psoriasis, on one day when the jaborandi was administered, the total amount of the urea diminished (14.30 in place of 24.30, which had been noted on the previous evening); on another occasion it increased (from 19.72 to 31.70). It increased on the days following the administration of the drug, so that in this case it appears probable that jaborandi favoured the elimination of urea. In a second case, of gout, the results were still more uncertain. The first trial gave a slight increase on the day the medicine was administered, 16.50 instead of 14.35, again increased on the following day to 21. The second trial, on the day the medicine was administered, gave a decrease (27 instead of 30), and this decrease continued during the following days, reaching 24.22. The third trial gave a diminution the day the drug was administered from 24.5 to 23, increasing on the subsequent day to 26.

Dr. Féréol agrees with Dr. Gubler, in considering jaborandi as a powerful sialogogue, and he thinks that if its sudorific properties are less continuous and powerful, they are still sufficiently important to place it above anything of the same description in the pharmacopœia. Dr. Féréol did not note any very important points in the medicinal action of this plant. However, the patient who took it fifteen times suffered no ill effects from it. He was a man fifty-seven years old, who had come into hospital for undefined pains in the lumbar region and legs; the kind of pains which are usually referred to chronic rheumatism, but which in his case may have denoted a deep-seated lesion depending on an old syphilitic affection; he was able to rise, walk about, and take his food like a man in ordinary health. Dr. Féréol first gave him some vapour-baths which agreed with him, and then replaced the baths by jaborandi, and the patient experienced a still greater improvement. After the sudoral and salivary crisis he felt freer, lighter, and more able to move about; the pains, however, returned in the night, or on the next day. Dr. Féréol did not feel justified in continuing so lowering a method of treatment, and tried iodide of potassium, which did not give the same relief as jaborandi.

In a case of acute rheumatism also, the patient, after salivation and sudation, said that he felt a lessening of his pains; and, if he had not at the same time complained of oppression and epigastric pain, which revealed an aggravation of the endocarditis from which he was suffering, Dr. Féréol would willingly have continued the administration of the medicine, in the hope of lessening the rheumatismal fluxion. In other cases, the action of the drug as a curative agent was *nil*, or even prejudicial. A gouty patient had an attack of gout a few days after the administration of the medicine. A neuropathic patient, suffering from congestive hypochondria, suicidal melancholia, and presumable beginning of general

paralysis, found his ordinary hemicranial pain redoubled in intensity.

Dr. Féréol is of opinion that, with all drawbacks, it is a great advantage to be in possession of a medicinal agent, of which the physiological effect is so immediately and clearly appreciable. It is, besides, difficult to believe that so powerful a physiological action should not be a force capable of being utilised in many cases.

Dr. Sydney Ringer and Mr. Gould publish, in the *Lancet* of January 30, the results of thirty-seven careful observations on the effects of this drug. The observations comprehended twenty on adults, whose ages varied from twenty to forty-five; and seventeen on children between three and ten years of age. To the adults sixty grains were given; to the children thirty, and sometimes sixty. These investigations have led to the detection of several new and interesting effects of jaborandi, and also to the conclusion that some of M. Robin's statements (see page 794 of the LONDON MEDICAL RECORD for 1874) are inaccurate. They show that children are very little affected by this drug. Generally thirty, sometimes sixty grains, were administered, giving both the solution and the dregs; and yet this dose often failed to produce any effect. In two cases only was the sweating abundant; in eight it was slight; in most, very slight, making the skin only a little moist; and in seven cases it excited no perspiration. Salivation was generally absent, and never more than to make the mouth rather moister than usual. There was very little flushing of the face, and this occurred only when perspiration was induced. The pulse was but slightly increased in frequency, from ten to sixteen beats, and this occurred only when the remedy acted on the skin. When the pulse was quick (and several of these children were convalescent and weak), the pulse was still less influenced, and sometimes even fell. In the earlier observations on older children, where the effects were well marked, the pulse was much more quickened. When the skin was rendered moist, the temperature generally fell, the fall varying from 0.6° to 2° Fahr. In eight of these cases it is noted that the child vomited, usually two hours after the administration of the medicine, but sometimes sooner. Occasionally the vomiting was repeated three times. When the vomiting was long delayed, none of the dregs of the medicine were rejected. Many of the children were sleepy during the stage of depression. In no instance were the bowels affected, nor did the medicine excite any cough. To sum up: in many cases the children were not at all affected in their rest; the symptoms were very slight, most strikingly so when compared with the marked effects of jaborandi on adults.

In the twenty observations made on eighteen adults, the perspiration in every case but two was most profuse, and in these exceptional instances it was free. It began in about ten minutes, and in one instance only was delayed for an hour. Salivation was absent in two cases only; in three cases it was slight; in the rest profuse, amounting in one experiment to twenty-seven ounces. In one case only the pulse was unaffected, though there was marked perspiration. In the rest the pulse was quickened from twelve to forty beats, the average being twenty beats per minute; the average increased frequency lasting two hours and a half.

The temperature was taken in nine cases, three in the axilla, the rest under the tongue. In every instance the temperature fell during the sweating, the

fall varying from 0.4° to 1.4° , the average being 0.9° , and lasting from one hour and a quarter to four hours and a half, and then becoming normal; that is, the temperature reached the point observed before the medicine was given. This was administered between 9 and 10 A.M. The average duration of the fall was three hours and a quarter. In one instance only did the temperature rise, and then only 0.4° , the rise lasting a very short time. On this point Dr. Ringer's and Mr. Gould's observations are opposed to those of M. Robin, who states that the temperature rises at first, and then remains depressed two or more days. This statement being quite at variance with their observations (for they found that in a few hours the temperature recovered itself), they noted the temperature in three men every three hours for three days before the administration of the drug, every hour during the action of the medicine, and every two hours for two days after the medicine. They found that in a few hours the temperature returned to the point noted before the drug was given, and on the two following days was the same as on the two days previous to the experiment. In one case only the flush of the face and neck was absent, and in every case save two the flush was followed by pallor and more or less depression or even prostration. In half the cases they noticed slight cough due to increased bronchial secretion; but this was always slight. In no instance did the medicine relax the bowels, so that its action on the intestinal mucous membrane must be slight. In one-half the cases the patients became decidedly sleepy, this occurring during the pallor, one, two, or three hours after the administration of the drug. A sensation of sickness, and sometimes decided nausea, occurred in two-thirds of the cases.

In several cases the sight was decidedly affected, in accordance with Mr. Martindale's observations on the effects of jaborandi. In three cases after the internal administration, the sight became decidedly affected, but the size of the pupil was unaltered. Mr. Martindale prepared an extract dissolved in glycerine for Dr. Ringer and Mr. Gould, which they introduced into one eye of thirty-one persons. In nineteen cases the pupil became decidedly contracted, the amount of contraction varying, in some being slight, in others reduced by one third, in two instances to one half. It was noticed that the pupil acted sluggishly in eleven cases. In a few hours the contracted pupil regained its natural size, but in one case the contraction was noticed twenty hours after the application. M. Robin found that the tears and nasal secretion were increased; but Dr. Ringer and Mr. Gould found in four cases only that the lacrymal and nasal secretions were increased sufficiently to attract attention. In eleven cases complaint was made of pain over the pubes, and in some instances this was severe, and was generally accompanied by a strong desire to pass urine, which afforded relief. A good deal of trembling, especially of the upper extremities, followed in two instances after the administration. This was the case with Mr. Martindale, and one man complained of much throbbing of the head the day following the experiment. Many patients complained of feeling alternately hot and cold or chilly. It will be seen that the later observations prove a marked antagonism between jaborandi and belladonna. Belladonna checks the secretion from the skin, the salivary glands, the mucous membrane of the nose, bronchial tubes, stomach and intestines, and dilates the pupils and contracts the

arterioles; jaborandi, on the other hand, increases enormously the perspiration and saliva, and in a much less degree, the secretion from the mucous membrane of the nose, the bronchial tubes, and the stomach and intestines. Belladonna excites delirium, whilst jaborandi often produces sleep. This antagonism was well displayed in four instances. On three occasions sixty grains of jaborandi were administered to three different men, and, when the perspiration and salivation were profuse, $\frac{1}{100}$ of a grain of atropia was injected subcutaneously. In five minutes the perspiration and salivation were considerably diminished, and in from ten to twelve minutes the skin was preternaturally dry and the salivation was checked, but in one case continued a little after the cessation of the perspiration. A lad was admitted into University College Hospital, poisoned by atropia, having taken one grain of the alkaloid five hours before treatment. His tongue and mouth were quite dry. A quarter of an hour after taking thirty grains of jaborandi his mouth became much less dry, and in an hour he was sweating freely, and his mouth was naturally moist. Belladonna, it is well known, arrests the secretion of milk, and Mr. Gould and Dr. Ringer were anxious to ascertain whether jaborandi was antagonistic to belladonna in respect to its influence on this secretion. They therefore administered thirty grains of jaborandi to a woman thirty-eight years old, confined of her ninth child four months previously. During suckling she had very little milk, and the quantity had become much less of late. The medicine was administered to her at 10 A.M. She had suckled her child seven hours before. In ten minutes the drug produced its usual symptoms; in half an hour her breasts, which previously were flaccid, became tumid and distended, and on pressure, yielded considerably more milk. In forty minutes the increase was still more marked, jetting forth in four or five streams. In eighty minutes the milk was less abundant, though considerably more so than before the experiment. The woman herself noticed the decided increase of her milk. To another woman, aged twenty-five, whose child was thirteen months old, two doses of thirty grains were given, as the first had no effect. She emptied her left breast every ten minutes by pressure, and each of the three first emptyings yielded 40 minims. As soon as perspiration and salivation became free, the quantity rose to 80 minims. The next time yielded 100 minims, the following 155 minims, the next time 80 minims. The salivation and perspiration at this time ceased. The next observation yielded 125 minims, the next 87 minims, the next 70 minims, and the last 40 minims. This woman, whose case is not included in those given before, complained of severe pain over the pubes, with desire to urinate, the pain immediately ceasing after micturition.

In some of their effects, however, jaborandi and belladonna agree. Thus, both flush the face and quicken the pulse; and both affect children much less than adults. Belladonna quickens the pulse by its paralyzing influence on the pneumogastric, and possibly by stimulating the sympathetic nerves. There is no evidence that jaborandi paralyzes the pneumogastric, or stimulates the sympathetics supplying the heart; but M. Robin has shown that it lessens arterial tension, probably by dilating the arterioles; and it is well known that dilating the arterioles, and thereby allowing the blood to pass more quickly from the arteries to the veins, quickens

the heart-beats. Hence it is very probable that the quickening of the pulse by jaborandi is due to its influence on the arterioles; and thus, instead of affording an instance of similarity of action between these two drugs, affords another example of their antagonism, for belladonna contracts the arterioles. While referring to the relations of these two drugs, it may be pointed out that both sometimes affect the bladder. Jaborandi causes pain over the pubes, with desire to pass urine, the pain subsiding when the bladder is emptied. These facts render it probable that jaborandi causes contraction of the bladder, for it does not augment the quantity of the secretion.

Jaborandi probably paralyses the sympathetic nerve, the effect being shown by the deep flushing of the face. M. Robin ascribes its effects to its influence on the sympathetic. But there are various reasons to doubt this conclusion. It is improbable that mere increase of blood could cause so great an increase of sweat and saliva. Belladonna flushes the face, but completely arrests the sweat. Again, it has been experimentally shown that belladonna will check the secretion from the submaxillary gland, although by irritation of the chorda tympani nerves the blood-vessels supplying the gland are dilated and full. It is true the flushing from jaborandi immediately precedes the outbreak of perspiration, but soon the flush declines, and is succeeded by marked pallor, yet the perspiration continues for hours, being often even more abundant than during the flush. To test whether the effects of jaborandi wore off by repetition, sixty grains were administered to a man on three consecutive days, and the symptoms were as marked on the third as on the first day. On each day, in a few hours, the temperature recovered from the depression, rising to the height observed before the medicine was given. This investigation would have been continued some days longer, but the man appealingly protested that he was undergoing more than his fair share of experimentation. In two other case sixty grains on two consecutive days were given, and the effects were as marked on the second as on the first. In one of these cases the temperature was observed, and on both days the temperature in a few hours recovered from its depression. These cases strikingly show the erroneusness of M. Robin's assertion that jaborandi causes a depression on the day following. On the other hand, the effects soon ceased in children, and sometimes the second dose failed to excite perspiration.

It may be suggested that the perspiration was due to the nausea and vomiting excited by the drug. Those who witnessed the effects of this medicine will certainly not ascribe them to the depression from nausea; but it may be added that the perspiration was too profuse to be due to mere depression and nausea. Moreover the perspiration occurred often some hours before the nausea or depression set in. Again, in children, though the drug in some cases caused much and repeated vomiting, there was no perspiration; moreover, in many cases, especially among adults, the full physiological effects of the drug were obtained without either nausea or depression.

Dr. Ringer and Mr. Gould tried in several cases a tincture from the leaves, and in one case an extract made from the tincture, and found these preparations as effectual as an infusion with the dregs. They found also that a strained infusion is equally efficacious with one containing the dregs; from which they conclude that the active principle is not the oil which is contained abundantly in the leaves.

In one case they gave a strained infusion of the root without effect; and in three cases an infusion made from the bark of the stem, with the dregs. The last preparation was active, though it appeared to excite more vomiting and to cause more depression than the preparations from the leaves.

Mr. John Tweedy also, in the *Lancet* of Jan. 30, gives an account of the effects of jaborandi on the eye. He remarks that, from the account given in the *Pharmaceutical Journal* of Jan. 16, by Mr. Martindale, of his personal experience of the physiological effects of jaborandi, it appeared that in addition to its diaphoretic and sialogogic actions, this drug was capable of exerting a decided influence on the accommodative apparatus of the eye.

In order to ascertain, if possible, what effect jaborandi really had upon the eye, some of the extract was placed within the conjunctiva of several patients. Of its effect on the pupil full particulars have been given above. Mr. Tweedy's attention was directed more particularly to the state of vision and the accommodation, and to the ophthalmoscopic appearances of the fundus oculi. As far as, however, the six or seven patients examined by him were concerned, he failed to find any constant or definite changes in the appearance of the eye beyond contraction of the pupil. One thing, however, was noticed—namely, that whereas the details of the fundus of the unaffected eye could be seen clearly without a lens behind the mirror of the ophthalmoscope, a weak concave lens was necessary to see clearly the details in the eye experimented on, thus showing some tension of accommodation.

Failing to elicit any definite or satisfactory information respecting the condition of the accommodation of the eye, in these patients, Mr. Tweedy determined to apply some of the extract to his left eye, and to note its effects. Accordingly at 1.30 P.M. he carefully tested the state of vision of his left eye, and found that he could read easily and clearly no. 1½ of Snellen's type from four inches (his nearest point) to twenty-two inches (his farthest point), and that $V = \frac{10}{10}$; i.e., at a distance of ten feet he could read no. 10 of Snellen's type. (Mr. Tweedy states, for the benefit of those not acquainted with Snellen's test-type, that whenever he expresses the state of vision or V by a fraction, the numerator will represent the distance at which he stood from the type, and that the denominator will represent the size of the type seen at that distance, or, more correctly, the distance at which that type makes an angle of five minutes at the optical centre of the eye.) He next made his left eye myopic by placing before it a convex lens of ten inches focal length, and found that he could see clearly and distinctly the fine vertical line of the dial he employs for estimating the degree of astigmatism, at a distance of nine inches. At 1.54 he placed within the conjunctiva a drop of the extract of jaborandi, which produced smart pain for about five minutes. After the smarting and lachrymation had ceased, he tested the state of vision of the eye, and found that at 2.0 the nearest point of distinct vision for 1½ Snellen had been approximated to three and a quarter inches, and the furthest point to twenty inches, while the fine vertical line could not be clearly seen, with the convex ten inches, at a greater distance than eight and a quarter inches. At 2.15, the nearest point for 1½ Snellen was at three inches, and the farthest at fourteen inches; and the greatest distance for the vertical line, with convex ten inches, was

eight inches. He could, at a distance of ten feet, make out some of the letters of 12 Snellen, but not even the letters of 30 Snellen were quite clearly defined. Just below the lower margins of each of the letters of 30 Snellen he could see, as it were, a fine shadow of half of each letter. There was at this time no perceptible contraction of the pupil. At 2.25 the nearest point for $1\frac{1}{2}$ Snellen was at three inches, and the farthest point at twelve inches. The left pupil was now noticed to be contracted to about half the size of the right. At 2.30 he could scarcely make out any of the letters of 15 Snellen at ten feet, and even those of 20 Snellen were not clear. He now observed that even those letters that he could make out appeared much smaller when viewed with the left eye than with the right, and that with the left eye they seemed to be at a greater distance from him than with the right. At 2.35 the nearest point for $1\frac{1}{2}$ Snellen remained at three inches, but the farthest point had receded to fifteen and a-half inches. The inequality of the pupil was *in statu quo*. At 2.40 he noticed that all objects, but especially distant ones, appeared much bolder, brighter, and better defined with his right eye than with the left, although under ordinary circumstances the vision of his left eye is more acute than that of the right. There appeared to be, in addition to the short-sightedness of the left eye, an actual impairment in the sensibility of the retina, producing imperfect amblyopia. At 2.50 the nearest point for $1\frac{1}{2}$ Snellen was at three and a quarter inches, and the farthest at sixteen inches. The fine vertical line could now be clearly seen with the convex ten at eight inches and one-eighth of an inch. At 2.55, $V = \frac{10}{12}$, and he could now decipher some of the letters of no. 10, all the letters being clearer and better defined. The inequality of the pupils, however, remained the same. At three, he could read even no. 8 Snellen at ten feet, and there was but little appreciable difference in the apparent size or distance of the letters when viewed with the right and left eyes alternately. The left pupil had relaxed a little, but was still smaller than the right. At 3.10 P.M. the nearest point for $1\frac{1}{2}$ Snellen was three and three-quarter inches, and the farthest point at eighteen inches. The vertical line could now be seen at nine inches with convex ten inches. At 3.30 the vision of the left eye had resumed its normal state, but it was not till after four o'clock that the left pupil had thoroughly relaxed.

From these facts he concludes that jaborandi locally applied to the eye causes (1) contraction of the pupil; (2) tension of the accommodative apparatus of the eye, with approximation of the nearest and furthest points of distinct vision; (3) amblyopic impairment of vision from diminished sensibility of the retina. These effects, however, do not last long. In Mr. Tweedy's case the approximation of the near and far points of distinct vision had declared itself in a quarter of an hour, and reached its maximum in about forty minutes. It then gradually subsided, and had entirely passed off, and the eye had resumed its normal state in about an hour and a half.

PATHOLOGY.

KLOB ON A PECULIAR AFFECTION OF THE BOWELS, LYMPHATIC GLANDS, AND LACTEALS.—The *Allgemeine Wiener Medicinische Zeitung* for December 15, 1874, contains a report of a paper read

by Professor Klob on December 11 at the Imperial Gesellschaft der Aerzte. He says he has met with five cases of an affection hitherto undescribed, although some analogous cases are recorded. In his cases, persons apparently healthy were attacked with symptoms which gave rise to the suspicion that they were suffering from typhoid fever. In one case the diagnosis fluctuated between this and enteritis. In another, acute peritonitis of a rapid kind was diagnosed. Of the five cases, four were brought into the hospital in a comatose and dying condition, and only one, a woman aged thirty-three, was one day under observation. Her symptoms consisted of violent pains in the hypogastric region, and the rapid occurrence of somnolence and coma with vomiting. There was a high temperature (103.6° Fahr.), and rapid pulse, becoming uncountable and thready. The patient died comatose.

Post mortem examination showed the following appearances. The body was strikingly pale. There were no changes in the nervous centres, and only accidental changes in the lungs, such as oedema; there were no particular cardiac changes; though in some cases the heart was much softened, this was not constant. The blood had lost its beautiful red colour, and had a livid hue. Microscopic examination showed increase of its colourless corpuscles. The liver was soft, in one case chocolate-brown. The spleen in all the cases was about half as large again as normal, though less than in typhoid fever. The stomach and valvulae conniventes of the jejunum showed striking changes. There were hæmorrhagic erosions in the former. Some of the transverse folds of the jejunum were swollen in the middle. This tumefaction was fairly resistant, and tolerably hard. The hardness was easily seen to be due to infiltration, beginning at the base of the fold, and extending into it. This infiltration consisted of blood. Sometimes just at the margin of the fold there was a slight loss of substance, covered with a small necrotic scab. This yellow, or yellowish-brown scab, was surrounded by a dark red colour. The adjacent fold had similar appearances, and in different degrees these were repeated, so that the further the bowel was examined in a descending direction, the less infiltration there was, the ileum being quite free from any such changes. The kidneys were always pale. The next remarkable appearances were found in the mesenteric glands belonging to the jejunum; they were as big as hazel-nuts, dark red, and had their capsules distended and separated from their substance by extravasations; and their parenchyma itself was infiltrated—as were their lymphatics, and the thoracic duct itself—with blood. Microscopic examination showed simple hyperplasia of the lymphatics, and adenoid formation in the jejunum.

To what category, says Dr. Klob, shall these cases be referred? The similarity of their symptoms and morbid anatomy leads one to infer that the affection is a specific one. We must not forget Virchow's leukæmia, and Wunderlich's pseudo-leukæmia; in the latter the lymphatic glands swell, and the patient becomes exhausted without any changes in the blood—the lymphatic glands exhibit simple hyperplasia. Langhans and Virchow both divide malignant lymphosarcomata into hard and soft. The former asserts that a certain malignity must often be attributed to quite simple hyperplastic conditions of lymphatic glands—and it seems that the soft lymphosarcomata run a less rapid course than the hard ones. Langhans points to metastases

as the proof of their malignity. The cases of pseudo-leukæmia do agree in many respects with those recorded above. But the rapid course, without metastases, the decided tendency to hæmorrhage and necrosis, distinguish these cases from pseudo-leukæmia, which is always more chronic in its course. Enteric fever, which is always a lymphomatosis, must next be considered. But these cases lacked most of the striking symptoms of typhoid fever—in which there is less tendency to hæmorrhage, if we except the epistaxis sometimes found in its early period, and the intestinal hæmorrhages sometimes found towards its close. The author considered these cases to belong to a group intermediate between pseudoleukæmia on the one hand, and typhoid fever on the other. Another case was adduced, in which the occurrence of cicatrices led to the belief that these changes had been previously passed through.

Professor Patruban, in commending the paper, pointed out how deficient our knowledge of the pathological anatomy of the lymphatic system is. He thought the appearances named might be explained by the tenderness of the stroma, and the thinness of the venous coats of the mesenteric glands compared with other lymphatic glands. The splenic enlargement is explained by the well-known functional homology of these organs—the lymphatics being found enlarged in cases in which the spleen is removed from animals. The permeability of the glands is much affected by various diseases, such as tuberculosis, cancer, melanosis, sarcomata, enteric fever, etc., so that it could often be predicted that such and such glands would bear injection, while others would not allow it.

W. BATHURST WOODMAN, M.D.

GHÉRINI ON A DEFORMITY BY EXCESS OF THE HANDS AND FEET.—Dr. A. Ghérini describes in the *Gazzetta Medica Italiana-Lombardia* for December 19, 1874, the appearances presented in a case of polydactylism. He refers briefly to Dr. Fort's description of the anomaly in his work on congenital and acquired deformities of the digits (Paris, 1869); to the case of a child observed by Saviard in the Hôtel Dieu of Paris, in which there were ten digits on each hand and each foot; to one described by Rueff, where each hand and foot had twelve digits; and to one observed by Voigt, where there were thirteen fingers on each hand, and twelve toes on each foot.

In Dr. Ghérini's case, the subject is a male child, aged three, one of twins; the other is a female, and is well formed. The parents are healthy, and there is no history of congenital defects of any kind in their families. The child is well developed and intelligent. His right hand has six metacarpal bones, each of which supports a finger with three phalanges; the thumb is absent. The first and sixth digits completely represent little fingers; while the two central digits, which are of equal length and size, resemble middle fingers. The three fingers on the radial side are completely united; the next is free; and the fifth and sixth (on the ulnar side) are joined. The carpus appears to be normal; the palm is large, but of regular shape; the wrist-joint is quite free; and the forearm is natural. The left hand resembles the right, but there is union between all the fingers except the third and fourth. The fingers can be flexed and extended at will, either all together or each series of

three separately; and the fourth finger of the right hand can also be bent and extended separately.

Each foot has nine toes. The middle one resembles the great toe in having only two phalangeal bones; it is free, and is larger than an ordinary great toe. The four toes on each side of it are united two and two. The outermost digits resemble the little toe. Nine metatarsal bones can be readily counted. The tarsus is very convex and wide, giving the idea that it contains a double number of component bones. Viewed from the plantar surface, each foot presents a rectangular plane surface wider near the toes than near the heel. Posteriorly, there is a longitudinal cutaneous sulcus, passing into the subjacent osseous structure, and dividing this to some extent into two unequal parts, of which the outer one is the larger. Each tendo Achillis is inserted into the larger portion of the os calcis. Extension and flexion of the foot on the leg are imperfect; hence the foot is always held at a right angle to the leg. The right leg is shorter than the left, and presents a slight concavity on the shin; the patella is dislocated outwards; the anterior superior spine of the ilium is lower on the right side than on the left, in consequence of the shortness of the leg. The flexor and extensor muscles appear to be single, the tendinous portion alone undergoing subdivision. In walking, the child supports himself and moves fairly well; but limps in consequence of the shortness of the right leg.

Dr. Ghérini believes that the most plausible explanation of the deformity is the partial fusion of embryonic germs.

MEDICINE.

KNECHT ON A SINGULAR NEUROSIS.—Dr. Knecht (*Berliner Klinische Wochenschrift*, October 26, 1874) relates the following case which he considers, from its characters and complications, to be unique.

The patient, a female, aged twenty-five years, was committed to the House of Correction, in Waldheim, in May 1873. At that time there was a slight want of symmetry in her appearance, and slight spinal curvature toward the right side. She had a slight cough. Nothing morbid could be detected in the lungs or heart, although she affirmed that she expectorated blood occasionally. She stated that she had never been seriously ill, and had not suffered from nervous affections. She knew nothing of her family history, as she had been estranged from her relations from childhood. In May and June of the previous year she had suffered from cramps, palpitation of the heart, and spitting of blood. In July she had a maniacal attack which lasted for many days. During a period of repose after this attack, the spitting of blood continued; there was, however, no evidence that the blood came from the lungs. About the same time, shortly before the catamenial flux, she experienced some ischuria from a spasmodic contraction of the urethra. For some weeks she remained the same, except that she was highly excitable, and phrenzy occurred on the slightest provocation. Soon afterwards she began to

complain of constriction of the œsophagus, occurring about the catamenial periods. In the month of September the temperature, which had previously been normal, rose to 40° Cent. (104° Fahr.), with occasional remissions of one or two degrees. On the 22nd of the same month, after a sleepless night, and the usual attack of cramps, the temperature was found to be at 40° Cent. (104° Fahr.), the skin of a bright scarlet colour, bathed in perspiration, and her whole frame in a state of tremor. This was concurrent with a vibratile movement of the thoracic walls, most marked in the fifth intercostal space. The point of impulse of the heart could not be distinguished, but over the cardiac region only, a diffused rhythmical movement could be felt. The most remarkable phenomenon connected with this part of the case was, that to those standing at the bedside, the heart's pulsations, about 170 in the minute, were audible at the distance of a mètre, like the ticking of a watch. The respiratory movements exceeded the normal number by from twenty to thirty. The carotid and temporal pulsations were distinctly visible. Mayer's sphygmograph showed a dicrotic pulse. This attack of tremor lasted about an hour; the violent action of the heart gradually subsided; but the profuse perspiration continued all day. The urine, voided after the attack, was scanty and contained blood-corpuscles. These seizures recurred daily, gradually becoming less severe. Auscultation found a considerably enlarged heart, exceeding much its ordinary limits. The later attacks were associated with tympanitis. The febrile condition continued. On one occasion, September 26, the temperature reached 42° Cent. (107·6° Fahr.).

On October 9 the temperature fell, and a great amelioration of all the symptoms followed. On the 15th, in consequence of mental excitement, there was a relapse, which continued until the 25th. These fluctuations were repeated until the end of December, 1873, when a discharge of purulent and sanguineous matter took place from the left ear.

At the beginning of 1874 a fresh symptom appeared, viz., a defect in vision, so that she could not count fingers at a distance of one mètre, there being double vision and photophobia. The pupils, somewhat dilated, were sensitive to light. In consequence of the resistance of the patient, a more minute examination could not be made. In two or three days it passed off.

The patient lost flesh, and became weak in the lower extremities, which also became slightly contracted. From the middle of January to February 8 a remission of all the symptoms occurred. From that time there occurred a relapse, with aggravation of all the morbid phenomena. It was observed that flushes of red colour occurred in the courses of certain nerves, e.g. the lower intercostal, the lumbar, and cutaneous of the thigh; sometimes on one side, sometimes on the other. Concurrently with menstruation, on March 12, there was another remission; from this time to the end of April, the symptoms had returned with greatly increased severity. Soon after this time, in consequence of her discharge from the house of correction, Dr. Knecht lost sight of her. She had latterly increased in weight; the skin had resumed its normal aspect; the contraction of the extremities had diminished.

The diagnosis suggested by the author is, an inflammatory condition of the spinal cord, resembling those cases described by Krishaber as 'neuropathie cerebro-cardiaque.' [It is much to be regretted, in

the cause of science, that this damsel's sentence of imprisonment had not been longer.—*Rep.*]

W. B. KESTEVEN.

BÉHIER ON INSANITY CONSECUTIVE ON TYPHOID FEVER.—Dr. Béhier has lately lectured on this subject, which is a very interesting one, both from a medical point of view and from its bearings on forensic medicine. It was brought under his notice by the presence in his wards of several examples of this condition. One of the patients was a female servant, aged twenty-two, who was brought in the hospital on September 4, on the eighth day after she was taken ill. She presented all the symptoms of undoubted typhoid fever; prostration, buzzing in the ears, vertigo, headache, diarrhoea, with rumblings in the right iliac fossa, swellings of the abdomen, and later on, roseola. The temperature was 104·36° Fahr. She had a dry tongue, red at the point and edges, and white in the centre; and also delirium. This delirium had shown itself under the influence of strong excitement, three days before the patient was brought to the hospital. It had not the characteristics of ordinary typhic subdelirium; but was a talkative delirium, with much agitation, mixed up with lively and constantly shifting ideas. Two days after the patient came into hospital—the tenth day of her illness—constipation was noted; which clearly arose from cerebral influence. On the thirteenth day some of the gastric and abdominal symptoms were improved, but the maniacal form of delirium continued with much agitation, incoherence, and hallucinations of the sight and hearing. On the following day the patient was better, and the delirium was quieted; but on October 8, the twenty-first day of the fever, a fresh crisis supervened under the influence of a new cause of excitement. Finally, on the 16th, the twenty-ninth day, after a period of calm, accompanied by weakness and a state of semi-imbecility, the agitation returned with fever (pulse 112, and temperature 102·9° Fahr.), leaving a condition of true imbecility, with hallucinations of sight and hearing and incoordinate movements. On November 30, one month after this last crisis, and two months from the commencement of the attack, the patient gradually recovered her health. But although every pathological trouble, every morbid condition had disappeared, her intelligence remained weakened, and she was in a kind of infantile condition.

The insanity of typhoid fever patients does not always show itself in this acute form at first. It sometimes commences by imbecility. This was the case with another patient in the ward, who without ever having had violent delirium during the evolution of her attack of typhoid fever, subsequently fell into a condition of hebétude or intellectual weakness without delirium, lasting during five months. The following case of insanity consequent upon typhoid fever is certainly a very remarkable one, both from its peculiar form and its complete cure at the end of three years.

A woman aged twenty-three, entered the Hôtel Dieu on November 20, 1871, the fifteenth day of an attack of typhoid fever. Her pulse then marked 64. The temperature was 96·8° to 98·6° Fahr. An anæmic souffle was discovered at the base of the heart. The only phenomena remarked, during the early days of the patient's stay in hospital, were headache, sleeplessness, and constipation (from the eighteenth to the twenty-second day). On the twenty-second day she

complained of distaste for food and refused to take any; her tongue was red and sore. On the twenty-second day, symptoms of hypochondria showed themselves. For the first time she talked of dying, and refused the hospital diet, probably having the notion that it was poisoned, though she pretended that the bad state of her teeth prevented her eating. The little she took brought on vomitings. She remained usually in an inert condition. On the thirty-first day her sight was affected. On January 18, 1872, acute mania showed itself. She got up half-dressed and left the ward, to which she could only be brought back by force. The insomnia and the vomitings of food continued, and there was cutaneous insensibility. Some soup was injected into the stomach by the oesophageal tube. Some days afterwards, vertigo came on. Paralysis of the bladder was discovered on February 4, and insensibility to contact and to external temperature in April of the same year. At this stage the patient made violent scenes every day, and reproached M. Béhier with wishing to kill her. On May 16 she suffered from great general exhaustion, and complained of pains in the head, with a sensation of heat and a painful feeling in the region of the stomach; the respiration was of a sighing character. She often lost recollection of the most recent events, did not know her own age nor that of her child, and gave such unmistakable signs of insanity that Dr. Béhier signed the certificate for her removal to a lunatic asylum. She was lost sight of for a long time, until she came to see M. Béhier, on December 4 last. She had been cured in the asylum, and at the present time only suffered from a certain amount of weakness of the sight and some sensations of formication in the fingers, with some localised insensibility; but her intellectual and emotional faculties had returned to her. She took care of and brought up her child, and testified gratitude for the attention she received in hospital.

BURCHARD ON WHOOPING COUGH.—Dr. Burchard, of Berlin, has published in the *Deutsche Klinik*, 1874, no. 41, an account of the manner in which, during the summer of 1873, he used the vapours of a solution containing from $1\frac{1}{2}$ to 2 per cent. of carbolic acid, for the treatment of this malady. The vapour is produced by boiling the above solution in the boiler of a Siegle's or some similar apparatus, and is directed three times a day into the widely opened mouth, at a distance of about twenty centimetres from the extremity of the tube conducting the vapour. The important matter is for the patient to draw a deep breath, so that the utmost amount of vapour may penetrate into the respiratory organs. The author succeeded with this plan with little children two years old, and did not meet with any marked resistance. The result was very favourable; the violent paroxysm of cough disappeared in two or three days, and the whooping cough was succeeded by a simple catarrh in the space of about eight days. This kind of medication often succeeds in a remarkable manner in catarrhal affections of the vocal cords, and proves equally useful in chronic catarrh of the trachea, especially when the expectoration takes on a putrid character, and presents the yellow tint peculiar to the production of fungi.

SURGERY.

STETTER ON RESECTION OF THE INFERIOR DENTAL NERVE.—Dr. Stetter (*Berliner Klinische Wochenschrift*, no. ii. 1875) reports a case in which Prof. Schoenborn, of Königsberg, removed a considerable portion of the inferior dental nerve by first dividing it in the mouth of the patient, and then by removing part of the anterior wall of the dental canal. The patient, who was a woman aged sixty-four, had lost most of her teeth before the age of thirty, when, in consequence of fright, she suffered during a period of three months from occasional attacks of severe cramp and painful convulsive movements of the limbs. When forty-eight years of age, she was again much frightened by the attack of a dog, and from that time suffered from frequently repeated attacks of spasm and pain on the left side of the face, the intervals between these attacks having, up to the time of her admission, become more and more frequent. When first seen by Professor Schoenborn, the patient, who was much emaciated, complained of very severe radiating pains on the left side of the face, especially about the lower jaw. The intervals between the attacks varied in duration from five minutes to a very few seconds, and during each attack the affected side of the face was fixed by muscular spasm. The woman was able to ease the pain by simultaneous pressure with her fingers on the inner surface of the lower jaw in the region of the aperture of the dental canal, and on the outer surface of the bone. After the patient had been treated for two weeks by injections of morphia without any good result, Professor Schoenborn decided to have recourse to neurectomy. As the patient referred the most intense pain to the region of the inferior dental canal, it was held that the cause of the affection might probably be found in the portion of nerve which was contained therein, and that a cure might be effected, or at least considerable relief afforded, by removing that portion. With this object in view, Professor Schoenborn first divided the inferior dental nerve in the mouth near the aperture of the canal according to Paravicini's method, then cut down upon the front of the lower jaw and removed with the chisel a portion of the anterior wall of the canal, and finally pulled out and excised a portion, about six centimetres in length, of the inferior dental nerve. In the first stage of the operation an incision was carried along the inner surface of the lower jaw over the course of the inferior dental canal from the aperture downwards and inwards, and afterwards for a short distance upwards towards the neck of the bone. The mucous membrane and periosteum were cut through and elevated along the whole of this wound, and the loose cellular tissue between the internal pterygoid muscle and the ramus of the jaw partly pressed on one side by the fingers and partly removed. After some slight bleeding had been suppressed, the lingual nerve could be seen, and behind it, on the outer surface of the internal pterygoid muscle, the inferior dental nerve and artery imbedded in cellular tissue. The lingual

nerve having been drawn aside by a small blunt hook, the inferior dental nerve was carefully dissected away from the artery and enclosed near the aperture by a ligature, the two ends of which were brought out of the mouth. The anterior wall of the canal lining these, in the second stage of the operation, was chiselled away over an extent of one centimètre and a half; the nerve was divided as far as possible above the aperture of the inferior dental canal, and then dragged out through the external wound. The dissection of the parts within the mouth and the division of the nerve were much facilitated in this case by the absence of teeth and the absorption of the alveolar process of the lower jaw, the conditions being similar to those met with in infants and very old people, and generally in edentulous subjects. On the first and second days after the operation there was no relief; on the third and fourth days the neuralgic pains were not quite so severe, and on the fifth day they ceased altogether. When seen six months after the operation, the patient was quite free from pain, and stated that she had not suffered from any relapse.

Dr. Stetter holds that Paravicini's method of dividing the inferior dental nerve within the mouth is to be preferred to the subcutaneous method, since in practising the latter it is difficult to avoid wounding the lingual nerve or the inferior dental artery. In conclusion, he argues that neurectomy in cases of neuralgia, though very uncertain in its results, may be considered a justifiable operation when applied as a last resource for the relief of very severe and intractable forms of this affection.

W. JOHNSON SMITH.

CUTTER ON THE ACTION OF FLOUR ON THE TEETH.—In an article entitled 'Does the Use of Flour promote Decay of Teeth?' in the *Boston Journal of Chemistry*, Dr. Ephraim Cutter discusses the question whether the prevalence of caries of the teeth is due to the use of wheat flour and to the disuse of whole-grain flour, and concludes in favour of the more extended use of whole grain as an article of diet for children, but at the same time urges the necessity of more extended experiments in regard to the influence of whole grains of wheat-meal, oatmeal, corn-meal, beans, etc.

[It has long been noted in this country that in those districts where the use of oatmeal (in place of wheat flour) prevails, we find children and adults with the best developed teeth and jaws; and so well recognised is the influence of oatmeal-diet upon the teeth, that many practitioners order its use as an article of daily diet for children, in cases where the dentition seems likely to be either retarded or imperfect.—*Rep.*] OAKLEY COLES.

TOXICOLOGY.

BRUGLOCHER AND EWALD ON POISONING BY NITRO-BENZIN, OR ESSENCE OF MIRBANE.—Dr. Bruglocher's case will be found in no. 1 of the

(Munich) *Aerztliches Intelligenz-Blatt* (22 Jahrg. January 5, 1875); Ewald's two cases in the *Berliner Klinische Wochenschrift* for January 4, 1875.

The former relates to a working soap-boiler, aged forty, who took five or six drachms of nitro-benzin, with about twenty times its bulk of spirit. He took part at 2 A.M., the rest at 7 P.M., on December 16, 1874. Loquacity was followed by drowsiness, which soon merged into complete insensibility. He was found quite unconscious at 7.30 P.M. At 8.30, when brought to the infirmary, all his limbs were paralysed, as in deep chloroform narcosis; the jaw was clenched tightly, and was opened with great difficulty. The skin was cyanotic; the lips of a violet blue. He foamed at the mouth. His breathing was stertorous and superficial. The pulse was scarcely to be felt. The heart's impulse and sounds were extremely weak. The surface was cold. The pupils were moderately dilated, insensible to light. The urine and fæces were passed involuntarily. He smelt strongly of bitter almonds. Vigorous cold affusion slightly deepened his inspirations, but did not rouse him. Then the stomach-pump was used; the fluid withdrawn smelt strong of bitter almonds. Three-fourths of a pint of water, with ten drops of strong solution of ammonia, were injected; also some strong coffee. At 9.30 the pulse and heart sounds were a little stronger; the mouth more easily opened. At 1 A.M. (17th) he seemed conscious, but his first brief replies to questions were at 5 A.M. At 10 A.M. he was still but half-conscious, and complained of pains in his pharynx (? from the stomach-pump). The odour of bitter almonds was still evident. In the course of the afternoon he perfectly recovered consciousness. On the 19th he was discharged cured. Bruglocher remarks that nitro-benzin, nitro-benzol, or nitro-benzid, a derivation of benzol, having the formula $C_{12}H_5NO_4$ [or $C_6H_5NO_2$], is an oily fluid, soluble in alcohol, not in water, smelling like bitter almonds, and much used in perfumery, etc., instead of the latter. It is known in trade as mirbane oil, essence of mirbane, or artificial oil of bitter almonds. Like other nitrites of the carbo-hydrates, nitro-benzin acts immediately upon the blood. All the symptoms can be easily explained by the saturation of the nervous centres with altered nutrient materials. According to W. Starkow's spectrum-analyses (Virchow's *Archiv*, vol. lii.) the blood of animals poisoned with bi-nitro-benzin shows the bands of hæmatin in an acid solution, as well as those of oxy-hæmoglobin. With nitro-benzin, however, these bands only occur in blood some hours after being taken from the body. Dr. Kreuser, of Stuttgart, gives the following *résumé* of the symptoms in nitro-benzin poisoning. 1. It acts as a direct irritant on the lips, tongue, and œsophagus, without implicating the mucous membrane of the stomach. In the case given above, the dilution with alcohol prevented this. 2. There is a period of latency of some hours, due to very slow absorption, the essence not being soluble in water. In one of Kreuser's cases, the vomit eight hours after taking the poison showed the oily fluid floating on it, and even the excreta had the odour. [In Ewald's cases there were, perhaps about an hour before unconsciousness, slight headache, and drowsiness, occurring in half to three quarters of an hour.] In the case above there was also a period of latency, though his excitement was probably due to the alcohol. 3. There is a remarkably strong smell of bitter almonds. [All the cases exhibit this. See the

remarks on urine, etc.] 4. Clonic and tonic spasms, observed in other cases, were wanting in this Schwabach soap-boiler; but he had strongly marked trismus. [The severer case of Ewald's had tonic spasms of the upper extremities; and afterwards a sort of passive but rigid flexion of the elbow-joints and fingers, without convulsions.] The rest of the man's muscles were as in deep chloroform narcosis. In the bath he doubled up like a fresh corpse. As regards treatment, the use of the stomach-pump was probably the most useful means, because of the slow solubility and absorption of the poison. Cold affusion was perhaps of use in exciting deeper inspirations.

Ewald has called attention in no. 52 of the *Centralblatt für die Medicinischen Wissenschaften*, for 1873, to his discovery that a large quantity of sugar can be detected in the urine of dogs and rabbits poisoned with nitro-benzin. He gives some details of two cases of poisoning by this substance in young women, aged twenty-two and eighteen years respectively. The first took about a drachm of commercial bitter almond oil at about 3 P.M. (February 16, 1873); the second about two and a-half drachms, at 9 A.M. (December 5, 1874). Both recovered, after about five and twelve hours' insensibility, and a further period of partial coma; the sequelæ being only slight headaches. Both cases were admitted to Dr. Frerichs' wards. It can scarcely be said that sugar was detected in the urine of either. The first urine passed in case no. 1 was about nine ounces in quantity, brownish-red, slightly turbid, free from albumen, of specific gravity of 1.020, and smelling strongly of bitter almonds. It held a large quantity of cupric sulphate and potash in solution, but did not reduce the copper [? glycogen, glycocoll, or inosite]. The urine of the second case was twice drawn off by catheter (six and eight hours afterwards) and a third sample passed spontaneously was also examined. The first samples equalled about half a pint together, with a specific gravity of 1.017. The next was similar; the quantity is not stated. It partially reduced, but did not decolorise, Trommer's solution, and failed to show appreciable amount of sugar by the polarising apparatus. The blood, taken by cupping, was brownish in colour, but gave no special spectrum-bands. Both patients were cyanotic—like a case of severe emphysema [not the tunica albuginea as in Müller's case]. There was an intense smell of the poison in the breath, vomit, etc., for three days. Even the urine smelt like it. Pulse, respiration, and temperature were but slightly affected [pulse 124 and 108, temperature 100.8° and 97.6° degrees, respiration 18 and 22 respectively]. The treatment consisted of analeptics in the slighter case, and of the stomach-pump in the severer one, with subcutaneous injections of camphor (dose not stated). It is thus evident that even the worst of these cases was comparatively mild. But the cases of Kreuser, Mackenzie, etc., show plainly how even apparently mild cases may rapidly terminate in death. Ewald says that, besides the symptoms mentioned by Kreuser (see above), we may have head-ache, stupor, vomiting, and extreme coma. Accelerated respiration, rapidity of pulse, rise of temperature, mydriasis, convulsions, rolling of eyeballs, sweatings, œdema of the face, involuntary stools, may or may not appear, and none of them are really prognostic, since recovery has taken place after everyone of them. The most striking *post mortem* phenomena are (says Ewald) the powerful odour of bitter

almonds, punctiform ecchymoses, and circumscribed brownish red or rusty coloration of the mucous membrane of the stomach, much hyperæmia, and strong *post mortem* rigidity. There seems no profound anatomical change in the intestinal tract, and the smell seems almost the only essential phenomenon. Ewald remarks that any convenient tube, such as that of a gas-lamp, may be used to wash out the stomach. [*Irish Hospital Gazette*, no. 16, August 15, 1874.] Next to this, subcutaneous injection of camphor or ether, inhalation of ammonia, warm frictions, cutaneous irritants, cold douche on the head and back should be used as in Short's case. Afterwards wine, coffee, tea, etc., may be introduced into the stomach. Ewald justly points out that it is absurd to forbid the sale of true essential oil of bitter almonds, and yet permit the free sale of this artificial and almost equally dangerous product. He gives the following references: Streeter, *Medical Times and Gazette*, December 16, 1854; Ellis, *Lancet*, February 16, 1863; Taylor, *Guy's Hospital Reports*, 3rd series, p. 173; Husband, *Lancet*, July 19, 1863, p. 167; Schenk, *Vierteljahrsschrift für Gerichtliche Med.* new series, vol. v., 2, p. 321; Müller, *ibid.* p. 341; Riefkohl, *Deutsche Klinik*, vol. xviii. p. 169; Mackenzie, *Medical Times and Gazette*, March 10, 1862; Letheby, *British and Foreign Medical and Surgical Review*, October, 1863; Idem, in *London Hospital Reports*, 1865; Barkley, *Lancet*, March 10, 1866; Kreuser, *Württemberg Medical Correspondenzblatt*, vol. xxxvii; Bahrdt, *Archiv der Heilkunde*, 1871, p. 320; Short, *British Medical Journal*, Aug. 15, 1868; Clifton Wing, *Boston Medical and Surgical Journal*, January, 1873; Helbig, *Deutsche milit. ärztl. Zeitung*, i. p. 36; Svederus, *Bruska* (? Svenska) *Läkarsällskapets Förhandlingar*, 1873, p. 128; Treulich, *Wiener Medizin. Presse*, 1870, p. 224; Lehmann, *Vierteljahrsschrift für Gerichtliche Med.* N.S., vol. xiii. He states that he cannot find any cases in French, after a careful search. [The reporter has found the following additional references. Casper's *Vierteljahrsschrift für Gerichtliche Med.*, vol. xvi. i. p. 1; Canstatt, vol. vii. p. 16.; New Sydenham Society's translation of Casper's *Forensic Medicine*, vol. ii. p. 50; Barker, *British Medical Journal*, vol. ii. 1861, p. 655; Letheby, *Pharmaceutical Journal*, vol. v. p. 130. Bahrdt's case (quoted above) may also be found summarised in the New Sydenham Society's *Biennial Retrospect*, for 1871-2, p. 449; Taylor's *Medical Jurisprudence*, 2nd edition, vol. i. p. 366. Why Ewald quarrels with Letheby, and credits him with only a single case, is not clear, unless he has never read his papers. His own discovery of sugar in the urine of animals thus poisoned, appears to the reporter to be valueless in a medico-legal point of view, since chloral-hydrate, chloroform, and a host of other substances which affect respiration, and even partial suffocation, by mechanical means, are all known to frequently produce glycosuria.—*Rep.*]

W. BATHURST WOODMAN, M.D.

MISCELLANY.

At the meeting of the Paris Academy of Medicine on January 19, the secretary announced that the Minister of the Interior had placed 4,000 francs at the disposal of the Academy. It is proposed to award 2,000 francs from this sum to the best paper on 'The Hygiene of Infants,'

the remaining portion to be used for the expenses of publishing the prize memoir and to give small prizes to other papers deemed worthy of such encouragement.

CHINCHONA IN INDIA.—The introduction of the cultivation of the chinchona plant into India has proved most successful. It was commenced in India in 1861. In 1874 there were 2,649,033 plants on the Government plantations of the Nilgiri Hills alone; besides private plantations, among which 234,531 plants and 469½ ounces of seeds have been distributed. In the same year 91,773 pounds of bark were supplied to the manufactory, for the preparation of quinine, in a cheap form, for use in India, the value of which was 2,294*l.*; and 1,181 cases of East Indian and Ceylon bark were sold in the London market. The tallest chinchona tree on the Nilgiri Hills is now thirty-two feet high, with a girth of twenty-eight and a half inches. It will be readily perceived that the beneficial results of bringing quinine and the other febrifuge alkaloids in the chinchona bark within the reach of the people of India can scarcely be overrated.

THE EXTREMES OF TEMPERATURE.—Up to the present day the maximum degree of cold ever recorded was on January 4 last, at Jakoutsch in Eastern Siberia. On that day the thermometer, as observed by a Russian merchant named Severow, registered $-59^{\circ}50'$ Reaumur ($-101^{\circ}8'$ Fahr.). A staff-surgeon affirms that he even noted one day a cold of -63° Reaumur ($-109^{\circ}75'$ Fahr.) in the same country, where the mercury is sometimes frozen for months together. At these times, according to Middendorf, the Siberian traveller, mercury becomes solidified and can be worked with a hammer like lead; iron becomes brittle, axes break like glass when they are used, it is impossible to chop wood; even fire itself seems to freeze, for the gases which feed it lose their heat. During the winter of 1819–20 it was impossible to go out without a mask, under risk of losing the nose or ears. In contrast to this low temperature are the extreme degrees of heat experienced in the north and east of the Sahara, at the foot of the Himalayas, in the valley of the Ganges, and on the interminable steppes of Afghanistan and Bucharia. Here the maximum heat observed has been 55° Reaumur ($155^{\circ}75'$ Fahr.) in the shade, and 70° Reaumur ($189^{\circ}5'$ Fahr.) in the sun. The Afghanisthan proverb says, 'Why, Allah, hast thou created hell? Hadst thou not already created Ghaznan?' Thus between the extreme heat in the sun in some regions and the extreme cold in others, the difference is from 125° to 130° Reaumur (281° to 292° Fahr.), that is to say 25° to 30° Reaumur, more than the scale which connects melting ice with boiling water. But, notwithstanding this extreme difference, man, by the aid of the appliances invented and popularised by science, is enabled to support the two extremes.

STATISTICS OF SUICIDE IN PRUSSIA.—The statistical office of Prussia has just published the following table of the suicides in that country, from 1869 to 1872, drawn up with characteristic minuteness of detail:—

	Men.	Women.	Total.
1869 . . .	2,570 .	616 .	3,186
1870 . . .	2,334 .	623 .	2,953
1871 . . .	2,183 .	540 .	2,723
1872 . . .	2,363 .	587 .	2,950

Suicide amongst men was on an average four times as frequent as amongst women. With regard to age, the tendency increases with age in men. The greatest number kill themselves between from ten to fifteen years of age, and between fifty and sixty. In women the tendency to suicide is most marked from fifteen to twenty years of age, and when they have passed their seventeenth year. Married people contributed 452 suicides per 1,000; unmarried persons above fifteen years of age, 339 in the 1,000; the remaining portion belonged to the category of widows and widowers, divorced persons, etc., classed by avocations. The suicides from 1869 to 1873 are thus sub-divided: Of 1,000, without distinction of sex, 204.6 were agriculturists, 244.4 in commerce, 158.3 were labourers and artisans;

63.5 were ship-builders, or otherwise connected with that calling; 52.9 belonged to the military and naval professions; 4.3 to forestry; 2.4 to the police; and 0.9 to the fisheries. It will thus be seen that, contrary to the usual impression of the healthiness of a life of labour in the open air, the agricultural interest contributed the largest proportion of victims. Most of these unhappy people either hanged or drowned themselves. When firearms were employed it was by men; the women chose poison or suffocation by the fumes of charcoal.

THE SWISS MEDICAL FACULTIES.—The three Universities at Bâle, Berne, and Zurich, each possess a faculty of medicine. German is the language in use at these Universities; but a fourth faculty has just been founded at the University of Geneva, where French is the medium of instruction. At Bâle there would seem to be considerable difficulties in the way of anatomical teaching, since the law only allows the dissection of suicides and persons who die in prison. What is known as the poly-clinic does not exist there. This institution, which is common to the other Swiss Universities and the majority of German Universities, to a certain extent resembles our out-patient departments, as by its instrumentation advice is given to out-patients. But this system is there supplemented by the students being sent to the homes of these patients when necessary, under the directions of the principal physician in charge. Instruction is given in the Swiss Faculties by ordinary and extraordinary professors named by the College of Professors, and appointed by the cantonal government, which defrays all the expenses of the University, and by free professors (*Privat Dozenten*), authorised under certain conditions to hold courses, remunerated exclusively by the pupils, which strengthen and complete the official teaching. The Swiss Faculties of Medicine, notwithstanding their justly earned repute, for they have reckoned amongst their professors Lebert, Billoth, Greisinger, Schiff, Liebermeister, etc., have very few students; there are scarcely 200 at Zurich, 150 at Berne, and 70 at Bâle. The grades obtained in any of the Universities do not immediately confer the right of practising medicine throughout Switzerland. As a rule, each canton grants the right of practising in its territory to the doctor who has obtained his diploma only after he has passed special examinations before a jury named *ad hoc*, by the communal authorities.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19*s.* 6*d.* Cloth Cases for binding the Numbers for each year may be had for 1*s.* 6*d.* each.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON ALCOHOL. By B. W. RICHARDSON,
M.D., F.R.S.*

(Continued from page 65.)

Disposal of Alcohol in the Organism.—We are brought now to one of the most important parts of our study. We see that, under favouring conditions, alcohol will oxidise in the presence of the air. We see that it will oxidise in two ways; actively, with the production of much heat and with the formation of carbonic acid and water; passively, with the production of aldehyde and acetic acid.

In the human body, do any similar changes take place? Throughout the whole of this vast sheet of the minute circulation there is ever in progress, during life, a process of slow oxidation of carbon and hydrogen, by which heat is produced, and carbonic acid and water are produced. The heat is proved by the animal warmth which is ever present in our bodies while we live; the carbonic acid and water, as products, are proved by their continued presence in the secretions from the lungs, skin, and other organs.

Alcohol, we have seen, is carried by the blood into this minute circulation. Is it possible that it can pass through that ordeal and undergo no chemical change? If it do undergo any changes, what is their nature? These questions have occupied the attention of many gifted minds; but they are not yet solved. Let me endeavour to put the position in which they stand plainly before you.

The earlier physiologists of this century came naturally enough to the conclusion that the alcohol taken into the body is consumed there with the evolution of heat. A certain development of heat in the superficies of the body, and a certain sensation of glow which follows upon the imbibition of spirit, lent countenance to this suspicion. But in course of time, independently of any knowledge of the effect produced by alcohol in the minute circulation of the blood, it began to be doubted whether alcohol was disposed of in the organism by its combustion. Some observers had noticed, in conducting the examination of the body after death from excess of alcohol, that the odour of the substance was present in the tissues, especially in the nervous tissue, and it was doubted whether the alcohol might not under some circumstances remain in the organism without undergoing any change at all. In 1860 three eminent Frenchmen, Lallemand and Perrin, assisted by Duroy, published a prize essay on alcohol, in which this view was maintained, or, as the authors would probably say, was originated; for in truth they were the first to state the view on direct scientific evidence.

From the result of many experiments, they came to the conclusion that alcohol taken into the living body accumulates in the tissues, especially in the liver and in the brain, and that it is eliminated by the fluid secretions, notably by the renal secretion, as alcohol. They sought in the different tissues for evidence of the secondary products of the oxidation of alcohol, for aldehyde, acetal, and acetic acid; and they found none of those products, except some acetic acid in the stomach, which acid, they concluded, was formed from the alcohol received directly into the stomach, and from the action exerted upon it there by the gastric juice. The experiments carried on by these inquirers were so numerous and careful, and the results they arrived at were so definitely stated that their labours were for a season accepted as conclusive by many men of science, and by the majority of the public. It was ascertained by other experimentalists that alcohol is eliminated by the system in the direct way, as alcohol, and the question of elimination rested as if it had been solved.

The interval of credence in these assertions was not very prolonged. An English physician soon commenced to cross a lance with his learned French peers, and to point out certain distinct errors in their results. I have no doubt many of you know, before I mention his name, that he to whom I refer was the physician who last year lost his life from the performance of his professional duties—the late Dr. Anstie. Respecting this observer, whose friendship I owned for many years, it is meet for me to pay this public tribute of respect; that no man I ever knew combined with vigour of mind, such incomparable industry and courage, or a more honourable regard for scientific truth and honesty. The subject we are considering has lost no investigator more ably learned for the work that still remains to be done.

From Dr. Anstie came the earliest expressions of doubt relative to this hypothesis of what is called the direct elimination of alcohol by the secretions, and from him have come the latest objections. His arguments have been sustained abroad by Schulinus, and in this country by Drs. Thudichum and Dupré, whose work on wine will, even in another century, be more highly prized, if that be possible, than it is now. The sum and substance of the labours of these observers is stated in a few words. They prove that while it is true that, under certain circumstances, alcohol taken into the body will pass off in the secretions unchanged, the quantity so eliminated is the merest fraction of what has been injected, and that there must be some other means by which the spirit is disposed of in the organism. In a lecture I delivered on this subject in the year 1869, I ventured to suggest, in commenting upon a series of Dr. Thudichum's remarkable researches, that perhaps one element of research was wanting to prove conclusively the fallacy of the direct elimination hypothesis. I thought that sufficient time had not been allowed between the administration of the spirit and the final determination made for it in the excreted fluids. It was not, I argued, shown how much spirit the tissues would hold unchanged. The objection was sound, and it has been renewed by more recent experiment.

In the last research conducted by Anstie, in which he was assisted by Dupré, the results of the experiments were unmistakable in their bearing on the points now under our consideration. The history of

* Cantor Lecture, No. IV. *Journal of the Society of Arts.*

these labours is recorded in full in the last paper written by Dr. Anstie, and published in the journal called the *Practitioner*, for July, 1874.

The test that had been commonly employed for determining the presence of alcohol in the fluid suspected of containing it, was the colour-test. A solution is made of this salt, the bichromate of potassa, with sulphuric acid. When to this solution alcohol is added, there is a change of colour from the brownish red to green; owing to the reduction of the chromic acid to the green oxide of the base chromium. By marking the difference of colour produced, a scale can be adopted which will show the extent of the reduction, and thereby the amount of the spirit that has caused the change. This process was improved by Dr. Dupré. He distilled the fluid in which alcohol was believed to be present, and then, after treating the distillate with the bichromate and sulphuric acid solution, he tested with a standard solution of soda for the amount of acetic acid which would be produced by the oxidation of alcohol were that fluid present.

This modification of test was and is a very considerable advance, since it enabled the observers to conduct their determinations with greater accuracy of detail. In the research they conducted with it two facts of singular interest were elicited. The first fact was discovered by Dr. Dupré. It was, that from the secretions of persons who do not drink alcohol at all a fluid can be distilled which affects the chromic test as if alcohol were actually present in the secreted fluids, and that this hitherto unsuspected product is oxidised into an acid, so like acetic acid it cannot be distinguished from it, and is apparently identical with it. To be plain, Dr. Dupré's discovery suggests that no man can be, in strict scientific sense, a non-alcoholic, inasmuch as 'will he nill he'—he brews in his own economy a 'wee drap.' It is an innocent brew certainly, but it is brewed, and the most ardent abstainer must excuse it. 'Argal, he that is not guilty of his own death shorteneth not his own life.' The fault, if it be one, rests with nature, who, according to our poor estimates, is no more faultless than the rest of her sex.

The second fact, which came chiefly from the labours of Dr. Anstie, was that from animals under alcohol, not one of the secretions, not all the secretions combined, yielded any more than a fractional amount of the alcohol that had been administered. The experiments were by necessity made on the inferior animals, but they supplied none the less conclusively the fact stated. It was proved that an animal, a terrier dog, weighing ten pounds, could take with comparative impunity nearly 2,000 grains of absolute alcohol in ten days, and that on the last day of this regimen he eliminated by all the channels of elimination only 1·13 grains of alcohol. This fact was of itself sufficiently remarkable, but another still more important remains to be told. In completion of his research after an animal had been treated with alcohol, as above described, Anstie killed it, instantly and painlessly, two hours after it had received the last quantity—ninety-five grains—of spirit. Then the whole body, including every fragment of tissue with all the fluid and solid contents, was subjected to analysis, with the result of discovering only 23·66 grains of spirit.

We are driven by the evidence now before us to the certain conclusion that in the animal body alcohol is decomposed; that is to say, a certain portion of it (and if a certain portion why not the whole?) is transmutable into new compounds. The

inference that might be drawn is fair enough, that the alcohol is lost by being burned in the body. It is lost in the body, and out of the body it will burn. If it will burn in the organism it will supply force, for it enters as the bearer of so much potential energy. In combining with oxygen, is there then a development of force or heat to the extent that would be developed in the combustion of the same quantity in the lamp, or from the distribution of it over the platinum black? At the same time, and in corroboration, is that product of its combustion, carbonic acid, to be discovered in the excretions? If there be heat, and if there be product of carbon consumed in oxygen, then alcohol must rank as a heat-forming food.

(To be continued.)

OERTEL ON THE TREATMENT OF DIPHTHERIA.*

General Treatment.—The treatment of diphtheria by internal remedies is based upon the same principles as those which guide the administration of internal remedies in other infectious diseases. As we possess no remedies which act directly to destroy or restrain the disease, or the virulent poison which causes it, we resort only at the present time to those agents which meet the existing indications.

For this purpose, therefore, cooling and antifebrile remedies should be chiefly given during the commencement of the sickness; these are, for instance, the mineral acids, dilute hydrochloric and phosphoric acids, and solutions of the sulphate or the muriate of quinine, in doses proportioned to the age of the patient and the vigour of the symptoms. If gastric symptoms usher in the disease, we can best quiet these by the administration of remedies containing carbonic acid gas, such as the effervescing draughts and various mineral waters. Where exhausting diarrhoea exists, we must combat it energetically at once, employing for this purpose, according to the intensity of the trouble, oily and mucilaginous substances, in combination with varying doses of opium, or solutions of tannin, alum, nitrate of silver, etc. If on the second or third day the fever diminish, and all complications have been successfully brought under control, our best plan is to wait, and not to resume active interference until new and then generally alarming symptoms develop.

In some cases already on the third or fourth day an alarming diminution of the patient's strength is observed; under these circumstances, we must give the preference to excitant remedies. When the pulse becomes frequent and lacking in force, and the heart-sounds are feeble and indistinct, we may resort to the use of quinine in large doses (from eight to fifteen grains); and should this succeed in strengthening the heart's action—which, alas! is very rarely the case—we may then change to other tonic remedies. Still even quinine may be continued for some time with advantage as a tonic, if administered in small doses of from three to four and a half grains in the course of the day. The stronger wines and nourishing diet, in the form of concentrated meat-broths, soups to which the yolks of eggs have been added; tea and coffee will also be found indispensable adjuncts. If under this treatment the patient do not improve, we may expect soon to see a still further depression of the vital forces, with indications of a

* *Ziemssen's Cyclopædia.*

pronounced sepsis, and symptoms of a fatal termination. At this point we may employ without hesitation large doses of the strongest irritants, as, for instance, sulphuric ether, Bestuscheff's tincture of iron,* and cognac, combined with the stronger wines, in the hope of exciting the feeble and irregularly acting heart to energetic contraction. In adults, sulphuric ether or Bestuscheff's tincture should not be given in smaller doses than ten drops every hour, if we expect to obtain the desired effect; and where collapse has begun to show itself, the same dose, or even a larger one (from twelve to fifteen drops), should be given every half hour not only during the day, but throughout the night, or at least the greater part of it. Even in children and young individuals, where as an exceptional thing death has not been caused by suffocation through the blocking up of the larynx and air-passages, but is, however, threatening the patient's life through septicæmia, we should not hesitate to employ these same remedies. The dose must then, of course, be reduced so as to correspond with the age of the patient and the intensity of the disease. The English recommend the administration of large doses of cognac in diphtheria under the same circumstances as those in which they have been in the habit of using it in typhus; and I have myself used it several times, with permanently good effects, giving in the course of a day to an adult from four to six ounces. Where cognac alone does not seem to agree with the patient it can be mixed with wine—Bordeaux, for instance, or Carlowitz—or with sweetened water, and given in conjunction with ether and Bestuscheff's tincture. In children it should be mixed with simple syrup or the syrup of orange-peel, in the proportion of one part of cognac to two of syrup; in this shape it is borne well.† In severe forms of pharyngeal diphtheria it will sometimes be necessary, even in children only three or four years old, to administer in the course of a day as much as an ounce or an ounce and a half of cognac; but the strong wines, such as Tokay, port wine, and strong Bordeaux, also act powerfully upon the heart, and their use is therefore highly to be commended.

It is extraordinary what large quantities of ether and alcoholic beverages may be taken, even by children, when the septic influence of the disease has lowered the excitability of the central organs and enfeebled the action of the heart. On the other hand, it is of course clear that if these be used prematurely and without judgment their effect may be the very reverse of what is desired; they may greatly increase the frequency of the pulse and the temperature of the body, they may call into existence symptoms of irritation of the brain and spinal cord, or they may induce serious disturbances of nutrition by the gastric complications which they cause. The first appreciable improvement produced by these remedies shows itself in a diminution of the frequency and a greater regularity of the pulse, together with a more natural temperature of the surface, especially noticeable at the extremities; the pulse gradually improves in quality, is fuller and stronger; the sensorium, if previously clouded, becomes clearer; and that, too, notwithstanding the enormous quantities

taken of ether and alcohol, which under ordinary circumstances would have produced a very marked obscuration of the faculties; and finally, the patient shows signs of returning strength and energy in all his functions.

If these manifestations of improvement be followed by genuine convalescence, we should, of course, gradually exchange these stronger stimulants for tonics, like quinine, iron, and good, nourishing diet; but at first it is well not to give up the cognac and strong wines altogether. As a rule, those patients whose constitutions have been deeply affected by the poison of the disease do not recover at once. After the lapse of a short time, and generally while the urine contains albumen, secondary paralysis or other sequelæ occur, and necessitate further treatment and constant supervision on the part of the physician.

If during the subsequent course of the disease, or even during the first few days, the patient manifest increasing signs of apathy and prostration, his pulse diminishing steadily in frequency until it reaches perhaps the rate of from forty to fifty beats in the minute, and the temperature of his body falling to a proportionate degree, it is hopeless to expect any assistance from stimulating remedies. Neither ether, musk, castor, nor camphor will prove of any avail in averting death.

Local Treatment.—In the management of the diphtheritic inflammation on mucous membranes, we have two objects to keep prominently before us: first, the character of the inflammation itself; secondly, the signs of reaction which precede the process of repair, the *vis medicatrix nature*.

The diphtheritic affection of the mucous membrane is distinguished as an exudative inflammation, which may increase from a simple catarrhal exudation to the pouring out of a fibrinous effusion upon the mucous membrane, or may even lead to the mortification of the tissue itself through the amount of inflammatory products and of micrococci; at the same time, the entrance of vegetable organisms into the blood and the absorption of injurious products of decomposition induce a general poisoning of the system.

Any therapeutic procedure, then, which in any way involves the danger of promoting these processes, will be already barred in advance. When retrogression of the pathological process takes place, and the false membranes become detached by the unaided efforts of nature, we find that this is invariably done through suppuration. The entrance of micrococci and the absorption of putrefying substances is prevented by a thick impermeable layer of pus-corpuscles, which at first infiltrate the superficial portions of the tissue, and ultimately, pressing forth from it, form a separating stratum of pus on the surface of the mucous membrane. The process of healing in the case of wounds which are the seat of diphtheritic infection, is accomplished in the same way, as I have repeatedly demonstrated in diphtheria of the respiratory mucous membrane; the removal of dangerous matters is accomplished here too by means of supuration.

After condemning local blood-letting and the application of ice as not only useless but as absolutely hurtful, Dr. Oertel next considers the effort to remove the seeds of the infectious material from the mucous membranes by mechanical detachment of the pseudo-membranes, or by destroying them with caustics or chemical solutions; and secondly, the aim to effect by astringents mainly a contraction of the inflamed

+ Chloride of iron dissolved in a mixture of one measure of ether to three of alcohol. It contains one per cent. of iron.—*German Ph.*

* Charles West, in the course of one day, once gave with good results nearly four ounces of cognac and an equal amount of port-wine to a child four years old.

mucous membrane and a limitation of the exudation.

Now, as far as concerns the mechanical detachment of the pseudo-membranes as being sources of inflammation, it certainly requires only a brief reference to the pathology of the process to make evident the uselessness and danger of such an interference. It cannot be enough insisted on that, in diphtheria of the mouth and throat, the contagious material is not confined to the false membranes, but is present throughout all the mucous membranes involved, as well as noticeably in the fluids of the mouth, in greater or less quantity. If now we attempt the mechanical detachment of the deposit, which in the beginning of the process is still quite firmly adherent, it always results in the production of small wounds of the surface of the mucous membrane, as shown by bleeding points where the individual capillaries have been torn. The possibility of an easier and considerable entrance of vegetable parasites and products of decomposition into the tissues is thus readily afforded, and, as proved experimentally, the life of the patient is put in far greater danger. The immediate result of such mechanical violence is, as a rule, the rapid reproduction of the pseudo-membranes, and at the same time they spread over a greater extent, owing to the increase of local inflammation and fibrinous exudation. But the final results where such a procedure has been resorted to are extraordinarily bad; the vast majority of patients, and, where the diseased process is intense, the whole of them, succumb to the infection of the general system.

In the attempt to combat the local process by cauterisation, we meet with a stage of things similar to what occurs when a simple mechanical detachment of the pseudo-membranes is attempted. This procedure was one of the earliest employed against diphtheria, and, since it agreed very closely with the theoretical views held on the subject, it was soon very widely adopted. Not only is it impossible completely to annihilate the diphtheritic contagious material, even by repeated cauterisation, when it has once become diffused throughout the whole buccal cavity, though every patch be never so carefully destroyed, but it is also impossible to combat the local disease by attempts to convert the specific inflammation into a simple one by these cauterisations. The immediate result of even the most prudent cauterisation is always a certain degree of mechanical violence to the inflamed mucous membrane; and the more circumspectly we endeavour to destroy all the greyish-white deposits, the more is the subepithelial tissue of the mucous membrane laid bare, the resulting slough failing to afford thorough protection in the way of a covering. In the cavity of the mouth, and in the mucus and saliva it contains, growths of micrococcus, as products of decomposition, are present in sufficient quantity to easily find their way into the lacerated parts of the mucous membrane, even though these be scarcely as large as a pin's head or only discernible with the microscope; and besides, the increased inflammation caused by the mechanical and chemical irritation furnishes a much more favourable soil.* I was enabled to observe these facts and prove them experimentally as long ago as 1864 and 1865. There can be no doubt, then, that the unfavourable results which have been attained on all sides by cauterisation, more or less energetically

practised, must put a stop to this procedure, even if in its stead we should be obliged to resort to the opposite, the purely expectant and symptomatic treatment.

But even the attempt to dissolve the pseudo-membranes chemically will prove practically valuable only so far as it can widen the space encroached upon by the membranes. But the danger of suffocation is scarcely to be feared when the throat alone is affected, however thick the membranous deposits may be, but only when the larynx and trachea are involved at the same time, and when, owing to the encroachment of the membranes, it becomes of vital consequence to remove them. With regard to the affection of the mucous membrane itself, as well in the case of the mouth and throat as in that of the other air-passages, the solution of the false membranes by chemical means cannot, as I have shown, have the least influence so long as the inflammation itself is not subdued. After dissolving the pseudo-membranes a new fibrinous exudation takes place, a second one forms, and even sometimes a third, without the treatment having gained any advance upon the disease. It is a necessary condition for improvement that after the removal of the false membranes the exudation also should cease, and a corresponding reaction, with energetic production of pus and new formation of cells, should take place upon the mucous membrane, which has been deprived of its epithelium and perhaps too of the uppermost of its layers of connective tissue. The danger too of a general systemic infection is just as little diminished by the chemical detachment of the pseudo-membranes as by the mechanical; and besides, in the former case the possibility of the introduction of masses of micrococcus and of decomposing substances into the mucous membrane, already laid bare and deprived of its epithelium, is greatly increased; the vegetable parasites and products of decomposition present in the mouth and pharynx are just as little destroyed by the chemical agents used for dissolving the membranes as by the caustics, which were formerly employed locally. When therefore it is not a question of treating a mechanical closure of the air-passages, or of averting the danger of threatening suffocation, we have no reason for using this procedure.

Lastly, it was quite early thought possible to obtain by astringents, especially in the form of gargles, 'an increase of the organic cohesion of the mucosa,' and thereby to antagonise the threatened loosening and dissolving of the tissue. Without considering the theoretical notion lying at the foundation of this treatment, no diminution of the exudation on the inflamed mucous membrane could be obtained by ever so energetic an employment of these means; but, on the contrary, through the irritation caused by these articles, an increase of the inflammation would be occasioned and kept up. Just the same conditions obtain here as in exudative inflammations in other mucous membranes; if an energetic treatment with astringents be employed in the acute stage, we have as a result an increase of the diseased process. But even supposing it possible to obtain a diminution of the fibrinous exudation by such means, still nothing would be gained in this way towards the cure of the processes of inflammation and decomposition in the mucous membranes. Neither does it affect the detachment of the pseudo-membranes and destruction of the masses of micrococcus, since these, unless nature interposes a

* Compare *Aertsl. Intell.-Bl.* 2,868. No. 31.

boundary by the formation of pus, may continue to grow unmolested within the tissues; nor is a stop thereby put to the decomposition of pathological products and the possible formation of injurious substances in the mouth and throat. Finally, as concerns the statistics of the empirical results, they do not testify in favour of the curative action of these remedies, since the astringents have proved themselves completely useless in every important case; and in the great number of cases which run an easy course, and are confined to a local manifestation, the favourable results are capable of an entirely different explanation.

(To be continued.)

CHRONIC LEAD-POISONING.

Of late the attention of physicians and chemists has been largely drawn to this subject on account of the increasing frequency of its occurrence, and on account of its great importance from a hygienic point of view. Not much that is new has been added to our knowledge of the sources of lead-poisoning, but many experiments have been performed which assist in explaining the exact action of the various kinds of water upon lead pipe, and much has been done to discover means of purifying water which has become contaminated with lead-compounds, and for substituting innocuous utensils instead of those which contain lead in their composition.

That distilled water when exposed to the air has a very powerful action upon metallic lead, is not a new observation. Thus, M. Pierre (*Journal de Pharmacie et de Chimie*, June 1874) detected $1\frac{1}{2}$ grain of the hydrocarbonate of lead in the distillate collected after passing steam through a coil of lead pipe. Nor is it new that the presence of certain salts in water modifies this action very greatly. The effect of various saline compounds has been studied at considerable length by M. Fordos (*Journal de Pharmacie et de Chimie*, July 1874). He finds that in potable waters which contain bicarbonate of calcium, the oxide of lead combines with a part of the carbonic acid, and there results a precipitate of the mixed carbonates of lead and calcium, which adheres to the surface of the lead pipe and prevents further contact of the metal with the water.

In water which contains the sulphate of sodium, the precipitate which results consists of a mixture of the carbonate and sulphate of lead. At the same time the water becomes alkaline to test-paper, and the filtered solution gives a black precipitate with sulphuretted hydrogen. Not only, therefore, has a precipitate of lead-salt formed, but there is also some lead in solution. This is explained in the following way. The oxide of lead, formed by the action of the water, reacts on the sulphate of sodium to form sulphate of lead and hydrate of sodium (liquor sodii); the carbonic acid derived from the air converts the latter into carbonate of sodium, which reacts upon the sulphate of lead to form carbonate of lead and sulphate of sodium again. The sulphate of lead is not absolutely insoluble in alkaline solutions.

With water which contains common salt, the result is analogous, a mixture of the chloride and carbonate of lead being formed. Analogous also is the action of chloride of ammonium, nitre, and nitrate of ammonium.

The action of water which contains gypsum (sulphate of calcium) upon metallic lead is very

slight, a precipitate of the carbonates of lead and calcium being formed upon the surface of the metal, protecting it from further action. If the water contain in addition to the gypsum 'oor of common salt, the action upon the lead is much greater. The sulphate of magnesium has the same action as the sulphate of calcium.

It will be seen, therefore, that the presence of alkaline salts in water can render partially soluble those salts of lead which are insoluble in pure water, such as the carbonates and sulphates, and thus partially counteract the beneficial effects of the earthy sulphates and carbonates in preserving the pipe from being further acted upon by the water.

M. Rafard states (*Journal de Chimie Médicale*, November 1874) that the simple addition of sulphuretted hydrogen is not a sufficiently delicate test for lead in water, since the hydrocarbonate of lead, which is formed by the action of pure water upon lead, and which consists of four equivalents of the oxide of lead, three of carbonic acid, and one of water, often exists in the water in a state of such minute subdivision that it cannot be seen by the unaided eye. In such a water, it is necessary first to dissolve the lead carbonate before it will be blackened by the sulphuretted hydrogen. In order to effect this solution it is only necessary, before adding the sulphuretted hydrogen, to bring the water to boiling, and add a few drops of a solution of tartrate of ammonium, which dissolves those lead-compounds which are insoluble in water. If these precautions be adopted, the brown colour of the sulphide of lead can be seen if only very small amounts are present.

To remove lead salts from water, M. Chevallier (*Annales d'Hygiène*, July 1874) recommends the use of animal charcoal. This method is especially applicable on board vessels, to remove salts of lead or copper from the water which is provided for drinking purposes by distillation. In many of the distilling apparatuses, the coil for the condensation of the steam is made of lead or copper, and the water thus condensed always contains a certain amount of the salts of the metal of which the coil is constructed. Many cases are recorded of what is termed 'dry colic' among the sailors on board of vessels which are provided with such an apparatus.

Experiments of Lowitz and others have shown that animal charcoal is capable of removing from water not only various organic matters, but also many mineral salts, such as those of lead and copper. The treatment of the water is as follows: To each hectolitre (about 26½ gallons) should be added thirty grammes (about one ounce) of well washed animal charcoal; the mixture should be well shaken or stirred several times, and then allowed to settle. The supernatant fluid is free from compounds of lead or copper, and is suitable for drinking purposes. Upon the same principle, by using charcoal filters for water which has flowed through lead pipe, tolerable security against lead-poisoning can be obtained, if care be taken not to overtax the filters.

It has long been known that one of the fertile sources of chronic lead-poisoning is the use of common glazed earthenware dishes for the preservation or cooking of food, especially acid fruits. The glazing of such vessels contains lead, which can be dissolved out by acids. M. Constantin, a chemist in Brest (*Journal de Chimie Médicale*, October 1874), has invented a new glazing which contains no lead and should be substituted for the lead glazings.

This is made by fusing a mixture of one hundred parts of silicate of sodium, fifteen parts of powdered quartz, and fifteen parts of chalk. To these ingredients may be added ten parts of borax, which renders the glass more fusible and adds to the brilliancy and durability of the glazing.

In the *Journal de Pharmacie et de Chimie*, for August 1874, is given a report by MM. Bergeron and l'Hôte of an outbreak of lead-poisoning in which twenty-six persons were affected. Two of the cases proved fatal. The disease was traced to the presence of lead in brine in which butter was kept. Six specimens were analysed, and found to contain amounts of the chloride of lead corresponding to from 2.3 to 7.5 grammes of sugar of lead to the litre of brine. Lead was detected in the intestines, liver, and brain of those who died. The existence of lead in the brain in cases of chronic poisoning has been denied by many authors. In the above cases, however, all the proper precautions were taken in performing the analyses, and the metal itself was extracted and weighed, so that there can be no doubt of its existence in that organ in some cases.

Dr. A. Manouvriez (*Recherches cliniques sur l'intoxication saturnine locale et directe par Absorption cutanée*, Paris, 1874) reports in detail thirty cases of chronic lead-poisoning, from the study of which he draws the following conclusions.

'1. In addition to general and indirect poisoning by digestive and pulmonary absorption, there exists a local and direct intoxication by cutaneous absorption, affecting the parts in immediate contact with the lead.

'2. This local intoxication manifests itself by neuralgic pains both articular and muscular, by cramps, trembling, tingling sensations, sensory and motor paralysis, and atrophy.

'3. This local affection, which in most cases co-exists with the general affection, can nevertheless in certain cases exist alone.

'4. These local symptoms can advantageously be combated by local external treatment, and prevented by hygienic precautions which keep the skin from contact with the lead preparation.

'5. The greatest caution is necessary in the employment of medicinal preparations containing lead local applications to the skin.'

Of the thirty cases reported, eight handled lead in the metallic form, as plumbers and type-setters, and twenty-two handled it in the form of white lead and minium. Three of the patients presented no symptoms of the general affection, no colic, no constipation, and no blue lines upon the gums.

In painters the local symptoms predominated upon the fore arm, affecting preferably the right side in those who were right-handed, and the left side in those who were left-handed. The symptoms, which were located exclusively or predominated at the points of contact with the lead, were motor paralysis (in twenty-two cases), paralysis of sensibility to pain (in twenty-seven), to touch and to temperature (in twenty-six), and to tickling (in twenty-two), trembling (in seven), cramps (in eight), pain (in nine), and tingling sensations (in four). After taking a sulphur-bath, the skin at the points of contact with the metal was coloured black in eight cases, although no colouration could be seen previously to taking the bath.

BINZ ON THE ACTION OF QUININE.*

In a pamphlet of seventy pages, Professor Binz furnishes a critical summary of the work done in this department since 1867, the year in which his book *Ueber das Wesen der Chininwirkung* drew general attention to the subject. Eighty-two papers are enumerated, of which no fewer than twenty-seven are from the pen of the professor himself. Most of the evidence is in favour of the views he originally put forth, which may be briefly summarised as follows.

Those processes of fermentation and putrefaction which are usually connected with the evolution of living organisms are checked or prevented by quinine, which exerts a paralyzing, or, in larger doses, a destructive action on most of the simpler organisms. The changes wrought by emulsion upon amygdalin, the conversion of albumin into peptone, that of starch into sugar, do not stand in any intimate relation to organised ferments; accordingly, they are not appreciably restricted by quinine. Further, some forms of protoplasm are less susceptible than others to the influence of the alkaloid: thus penicillium thrives in solutions of quinine containing a trace of sulphuric acid; the *amæba* of salt-springs and the *euglenæ* of salt-marshes are but little affected by it.

In close connection with this toxic effect of quinine on lower organisms, stands its action on leucocytes. It is able to paralyse their spontaneous movements and to check their migration into inflamed parts.

Quinine cures the various manifestations of the malarial cachexia by acting directly upon the central cause of those manifestations, whether this be an organised germ or some albuminoid material in a state of change. Its curative action is not exerted through the nervous system. Indeed, the effect of quinine on the brain, cord, and peripheral nerves, has been much exaggerated, and is chiefly indirect. Thus the lowering of the reflex excitability of the cord exhibited by frogs under the influence of the alkaloid (Eulenberg), and supposed to be due to stimulation of the inhibitory centres in the brain (Chaperon), is really to be ascribed to the depressant action of the drug upon the heart, and the consequent diminution in the supply of blood to the grey matter of the cord. The tinnitus, vertigo, drowsiness, and other symptoms of quinism in man may possibly be due to a partial anæmia of the brain.

The power of lessening the size of an enlarged spleen which quinine undoubtedly possesses, has been shown to be independent of the nervous system by Mosler and Landois; after dividing all the nerves going to the spleen, they made the organ contract by administering the drug. Mosler explains this fact by supposing that the alkaloid stimulates the contractile elements directly. Binz, without entirely rejecting this hypothesis, is inclined to believe that the mode of action is more complex, that the drug paralyses the irritant miasm in virtue of its antiseptic quality; that it limits the corpuscular proliferation in the splenic parenchyma; and, finally, that it checks the processes of oxidation which go on there. The functional activity of the organ being thus reduced, its blood-supply is secondarily lessened, and it shrinks in bulk.

The antipyretic effects of quinine are not due to

* *Das Chinin, nach den neueren pharmakologischen Arbeiten dargestellt.* Von C. Binz. Berlin, 1875.

any mysterious operation on the brain or vaso-motor nerves. Neither can they be explained by its depressant action on the heart. It has been experimentally proved that, when the temperature of fevered animals is lowered by quinine, the fall is due, not to any increase of the heat given off, but to a diminution of the heat generated in the body. And this is owing to the power which quinine possesses of limiting the oxidation of the azotised constituents of the organism. The exact nature of this power is still obscure. Quinine undoubtedly hinders the hæmoglobin of the red corpuscles from yielding up its oxygen to the tissues, and prevents the characteristic action of ozone upon egg-albumin. Moreover, Ranke and others have demonstrated that the excretion of uric acid and urea is much diminished by quinine, and that this diminution can only be accounted for by a reduced production of nitrogenous excreta in the body. The effect of the alkaloid on the amount of carbonic acid exhaled is still under investigation; it does not seem to lessen it to any great extent.

The therapeutic value of quinine in various septicæmic conditions, whether accidental or artificially induced, is unquestionable. It probably depends on several causes; but its hostility to septic organisms, to oxidation, and to inflammatory processes, will probably suffice to explain it.

The last part of the pamphlet is taken up by clinical evidence of the value of quinine in surgical septicæmia (Socin), enteric fever (Leibermeister), hay-fever (Helmholtz), small-pox (Ladendorf), whooping-cough (Binz), and practical hints on dosage and mode of administration. The author recommends large doses, and brings facts to show that even very large doses do not necessarily give rise to dangerous symptoms; e.g., fifteen grains to children under two years of age, seventy-five grains (!) to adults suffering from pneumonia (Jürgensen).

E. BUCHANAN BAXTER, M.D.

ANATOMY AND PHYSIOLOGY.

PINK AND HEIDENHAIN ON DIABETES MELLITUS AND THE FORMATION OF GLYCOGEN IN THE LIVER.—H. Pink (*Inaugural Dissertation*, Königsberg, 1874; abstract in *Centralblatt für die Med. Wissensch.*, no. 3, 1875) investigated how long a rabbit must fast in order to be certain that the liver contains no glycogen; and in this way that he tested one part of the liver for glycogen, the second he digested with saliva, and analysed the sugar contained therein. He found that five days were sufficient to remove every trace of glycogen. A solution of ordinary grape-sugar (two to three grammes) was injected into the vena meseraica of a rabbit which had hungered for five days, and the animal was investigated in from half an hour to an hour and a half afterwards. The investigation of the liver was investigated in the same way as formerly, only the weight of the piece of liver in boiling-water was estimated, and the sugar was also estimated in the first portion. The quantity of glycogen was now estimated. In all cases glycogen was found in the first piece of liver, and only traces or little sugar; in the second piece plenty of sugar. In that the sugar in the second piece can only have been derived from glycogen, the experiments confirm the results of Schöffer, that sugar injected into the vena meseraica passes

into glycogen. Made aware that the grape-sugar contained dextrin, the author repeated the experiments with pure sugar, and once with glycerine, and arrived at a completely different result; the first piece of liver contained no glycogen, the second not more sugar than the first. Afterwards the author injected pure sugar as well as glycerine into the stomach, and found a plentiful formation of glycogen. The author concludes that sugar as well as glycerine are changed in some way by the stomach, and their change into glycogen rendered more easy.

In the experiments of Heidenhain (*Inaugural Dissertation*, Königsberg, 1875; abstract in *Centralblatt für die Medicinischen Wissenschaften*, no. 3, 1875) chemically pure grape-sugar was injected into the vena meseraica of fasting rabbits, to settle the question whether sugar actually passes into glycogen. The author investigated a piece of liver each time before the operation, or a few minutes after the injection; the second larger piece of liver after the animal had lived from twenty to forty-five minutes. As with Pink, the weight of the piece of liver was taken, and the glycogen estimated quantitatively; the result, with one exception, was at one time more, at another less increase in the glycogen. Thus far his results stand in direct contradiction to those of the former paper. Nevertheless, the quantities of glycogen were always relatively smaller in proportion to the quantity of sugar injected. This was four to nine grammes (61 to 138 grains); the glycogen obtained was only 0.05 to 0.156 grammes (0.2 to 2.34 grains). Schöffer's view that the liver can change 0.12 grammes sugar into glycogen in a minute, cannot therefore in this form be correct. The small quantity of glycogen leads the author, like Pink, to think that sugar undergoes some kind of change in the stomach or intestine, which render it more fit to be transformed into glycogen. To test this idea the author ligatured the pylorus of rabbits (*b*) and then injected sugar, intact animals serving as a control (*a*). In fact the quantity of glycogen became markedly less after ligature of the pylorus, the urine contained no sugar, whilst it generally contained sugar. The quantity of glycogen in *a* was 0.119, 0.636, 0.206; in *b*, 0.014, 0.015, 0.075, 0.099, 0.085 grammes.

HEUBEL ON THE 'SPASM-CENTRE' OF THE FROG AND ITS RELATION TO CERTAIN DRUGS.—E. Heubel (*Pflüger's Archiv*, vol. ix., and abstract in *Centralblatt für die Med. Wissenschaften*, no. 59, 1874) remarks that the tonic form of contraction occurring in the frog has been more studied than the more seldom occurring clonic convulsions. Former investigations had not rendered it certain whether there existed in the central nervous system a circumscribed spot whose stimulation was followed by general clonic spasms. The exposed nervous centres of strong frogs were stimulated by simple, more or less gentle, contact with the head of a needle. Stimulation of the cerebrum, of the thalami optici, of the cerebellum, never gave muscular contractions; that of the corpora quadrigemina produced movements of the eyes, of the membrana nictitans, and bending of the head forwards and downwards. If the anterior broad part of the upper surface of the medulla oblongata (sinus rhomboideus), were touched with the head of a needle, the frog showed as 'an unmistakable sign of pain,' a sudden powerful contraction of the whole body, so that after removal of

the needle the animal lay spasmodically flat upon the table. It remained for a longer or shorter time in a comatose condition, which sometimes passed into death. More sensitive to the same method of stimulation was the posterior angle (that nearer to the spinal cord) of the sinus rhomboideus. Upon touching this spot, the animal constantly uttered a loud cry, followed by trismus, general convulsions, clonic mixed with tonic spasms, whereby all muscles were thrown into action, the animal being caused to roll over, and it continued to contract upon the table. After the spasmodic seizure had passed off, the frog remained some time in the sometimes very remarkable position, until almost completely motionless, and reflex sensibility had almost disappeared. If the animal recovered, the collective symptoms could again be produced, but not with the same intensity. The same results were obtained if, before the stimulation, the medulla oblongata, cerebrum, thalami optici and corpora quadrigemina were removed; sometimes also by a simple section through the medulla oblongata, which probably acted as a stimulus to the hypothetical spasm-centre (*Krampf-centrum*). As the anterior limit of this centrum may be indicated an imaginary line which divides the sinus rhomboideus into an anterior and posterior half, whilst the posterior limit certainly does not lie more than one or one and a half millimètres (.04 or .06 inch) behind the calamus scriptorius. Concentrated solution of chloride of sodium also produced general bodily convulsions, which passed into tetanus. It could be proved that the centre for these muscular contractions is to be sought in the medulla oblongata. After the assumption of a special 'spasm-centre' (Nothnagel) was capable of being regarded as probable, the idea that this action of picrotoxin, nicotin, and other bodies upon the organism is caused through this centre lay at hand. The author corroborates the proofs already offered by Röber, that picrotoxin, in that it produces the known characteristic spasms, acts as a stimulus to the ganglionic apparatus of the medulla. The same is also true (contrary to the ordinary assumption) of nicotin. After careful separation of the brain from the spinal cord in the frog, it is said that nicotin spasms no longer take place; on the spinal cord this alkaloid acts only as a depressant, and to such a considerable extent, that always (when the medulla oblongata is retained) only a single spasmodic seizure is produced, and repetition and increase of the dose do not cause a second attack. As by mechanical irritation, and by chloride of sodium, picrotoxin and nicotin, so also by caustic ammonia, carbonate of ammonia, bromide of ammonia, and chloride of ammonium general clonic spasms could be produced, whose point of origin was undoubtedly placed in the medulla oblongata. In all the above experiments, it remains doubtful whether the spasms were produced reflexly or directly. Several circumstances support the latter view. In all experiments the reflex sensibility was considerably diminished, whilst in undoubtedly reflex spasms (*e.g.* those produced by strychnin) the reflex sensibility is almost always increased. Further, artificial respiration was without effect on the spasms produced by nicotin, whilst reflex spasms, as is known, are cut short by apnoea.

The author adverts to the fact that, under strong stimulation of peripheral sensory nerves, certain actions of the large nerve-centres are inhibited. Corresponding to this he explains the diminution of

the reflex sensibility and of the sensory activities during and after stimulation of the 'spasm-centre,' 'this most sensitive point of the whole cerebro-spinal axis,' as a direct consequence of stimulation of the medulla itself.

WM. STIRLING, D.Sc., M.B., Edinburgh.

RECENT PAPERS.

- On the Science and Art of Embalming the Dead. By Dr. B. W. Richardson, F.R.S. (*Medical Times and Gazette*, January 2, 16, and 30.) [After giving some account of the processes formerly employed, Dr. Richardson gives full practical directions for the performance of this operation, according to a plan perfected by himself.]
- On the Natural Connection between the Functions of the Lungs and Heart. By Dr. V. Chirone. (*Lo Sperimentale*, January, 1875.)
- On the Physiology of the Act of Vomiting. By Dr. Broadbent. (*Practitioner*, February, 1875.)
- The Physiology of Micturition and Retention of Urine. By Mr. Henry Power. (*Practitioner*, January.) [An account of the recent experimental researches of Budge, Goltz, and others, demonstrating that the action of the bladder is directly controlled by an excito-motor centre of nerve-force situated in the spinal cord, nearly opposite the fifth lumbar vertebra, and that in animals the bladder is almost independent of the brain, and in man is only secondarily influenced by it.]
- On the Similarity between the Red Blood-Corpuscles of Man and those of certain other Mammals. By Dr. J. J. Woodward. (*Monthly Microscopical Journal*, February.)

PATHOLOGY.

WICKHAM LEGG ON SOME REMARKABLE CASES IN MORBID ANATOMY.—Under this title Dr. Legg has reprinted some cases of great interest from volume x. of the *St. Bartholomew's Hospital Reports*. As these are easily accessible to most readers, it seems sufficient to give a brief abstract, referring for details to the original.

The first case is that of a woman, aged thirty-seven, with bronzing of skin, increasing weakness, loss of flesh (having lost four stone in weight in about eighteen months) and vomiting; in whom no right suprarenal capsule could be discovered, whilst the left had undergone such extreme fibrous degeneration that it resembled a mere shell with no contents.

The second case is one of meningitis, and blocking of the artery of the Sylvian fissure on the right side, with erysipelas of the head and face. [The reporter begs to submit that colpitis more properly signifies what is commonly called vaginitis, though qualified hereby by the word cavernosa, and applied to inflammatory changes in the cavernous sinuses. In so saying he is quite aware that Dr. Legg may plead authorities as precedents: but he thinks it is better to avoid ambiguous words.]

Case 3 is one of ulcer of the stomach with fatal hæmatemesis, from perforation of the splenic artery. The patient was a woman, aged thirty-four, who had suffered from sickness for years. The stomach was sacculated, in a tripartite fashion. The secondary stomach, to all appearance, may have been congenital.

Two cases of poisoning by hydrochloric acid come next. In the first, a man aged fifty took about three-quarters of a teacupful of strong hydrochloric acid (three to four ounces?). In the second, a woman, aged thirty-five, took 'about a teacupful.' Both died four or five hours after admission, and apparently about six or seven hours after swallowing the acid. In both

the pharynx and œsophagus were whitened, whilst the mucous membrane of their stomachs was blackened. In the man the stomach was thinned and dilated; in the woman the stomach was contracted, and its coats thickened. There was extensive fatty infiltration of the liver in the man, like phosphorus-poisoning.

Case No. 6 was one of mitral constriction, with well-marked concentric hypertrophy of the left ventricle of the heart, plugging of artery to the left Sylvian fissure, and softening of the brain; in a man aged twenty-three, whose history was unknown.

The seventh case is noteworthy, from the fact of a round-celled sarcoma of the pyloric half of the stomach, adjacent part of the liver, omentum, etc., occurring in a girl aged seventeen, in Dr. Southey's wards. There was fibro-cystic degeneration of the ovaries. This case appears almost, if not quite, unique, unless Wilkinson's, quoted by Dr. Legg (from the *Monthly Journal of Medical Science* for 1841, p. 23) be analogous, which seems doubtful.

The eighth is one of cancerous ulcer of the stomach, with suppurative thrombosis of the portal vein [pylephlebitis], in a man aged sixty-three, under Dr. Southey's care.

The next case, in a single Jewess, aged twenty-three, was one of a gall-stone of the size of a hazel-nut, impacted near the duodenal papilla of the common bile-duct—dilatation of all the biliary ducts, with abscess of the left lobe of the liver, finding its way into the pericardium and right pleura. In this case there was but slight jaundice, but Dr. Legg remarks that the ducts communicated freely with the abscess. During life all the signs of fluid in the left pleura were present, but no fluid was obtained by paracentesis thoracis; this was explained *post mortem* by the height to which the diaphragm was pushed by the abdominal disease. [The Reporter lately had a child under his care, in whom empyæma of the right side was diagnosed by several experienced auscultators. Paracentesis was performed with considerable relief to the dyspnoea, but after death the disease was found to be an abscess between the diaphragm and upper surface of the liver.—*Rep.*]

Case 10 is a case of hydatids of the liver, omentum, and recto-vesical pouch, jaundice, and xanthelasma (vitiligoidea) of the tongue, eye-lids, and skin of the right temporal region (zygoma), the helix of the right ear, the nape of the neck, bend of the elbows, ball of the thumbs, ball of the left little finger and its ulnar extremity, root of the penis at the junction of the skin of the scrotum with the abdomen, perinæum, and the flexures of the fingers of both hands. There was none below the perinæum. In the eyelids, the part towards the inner canthus was most affected. In the tongue there was one yellow raised spot on the dorsum, and three or four yellowish white ones, varying in size from a split-pea to a sixpence along each side. There was a small cluster at the commencement of the œsophagus, and one yellow spot at the fore part of the larynx. There were also yellow patches in the peritonæum. The microscopic anatomy of the patches on the tongue corresponded with that of the xanthelasmic patches on the skin. In the great omentum there was a hydatid cyst, adherent also to the sigmoid flexure of the colon, of the size of an adult kidney, containing many daughter-cysts. There were three hydatid cysts in the liver; two sterile, one as big as a cocoanut, one of the size of an orange, contained shrivelled membranes, and a quantity of dark solid pigment.

The hydatid cyst between the bladder and rectum was as large as a child's head. It contained no daughter-cysts. [The Reporter has known such cysts, from causing retention, to be tapped for a distended bladder, by men of considerable experience. It is much to be wished that other pathologists attached to large hospitals, whether in London or the country, would give us similar brief accounts of the remarkable cases which from time to time come before them in the *post mortem* theatre, with brief abstracts of the symptoms in life, as far as known. Such records are invaluable to busy men who cannot spare time to read long reports or extended treatises.—*Rep.*] W. BATHURST WOODMAN, M.D.

NORDENSTRÖM AND AXEL KEY ON A CASE OF SARCOMA IN THE VERTEBRAL CANAL; SCURVY WITH HÆMORRHAGE IN THE SPINAL CORD AND ITS MEMBRANES.—Dr. Nordenström relates in the *Hygiea* for 1874 (abstract in *Nordiskt Medicinskt Arkiv*, vol. vi. no. 32) the case of a patient aged seventeen, in whom symptoms of scurvy appeared at Christmas, 1873. At the end of March, 1874, he had paresis of the lower limbs, which was soon followed by complete paralysis of these parts, with paresis of the bladder. In a short time the upper limbs became first paretic and then paralytic; he became gradually weaker, and he died early in April. At the necropsy, besides the usual indications of scurvy, there was found in the spine, at the level of the seventh, eighth, and ninth dorsal vertebrae, a tumour which surrounded the dura mater for about two inches on its posterior and lateral aspects. It was loosely adherent to the dura mater, resembled a decolorised blood-clot, was of a greenish-grey colour, and had a thickness of about one-fifth of an inch. Some small fresh blood-clots were found lying on the dura mater in the upper cervical region.

A careful examination of the parts was made by Professor Axel Key. He found that the tumour was closely connected with the fatty tissue surrounding the dura mater, to which it was only loosely adherent. Microscopic examination showed it to be a round-celled sarcoma, with feebly developed ground-substance and numerous hæmorrhagic deposits. Sarcomatous vegetations could be distinctly seen in the adipose and connective tissue around the dura mater. At the part corresponding to the tumour, the dura mater had undergone sclerotic thickening. Coagulated extravasated blood lay in the sub-arachnoid space; and the cord itself presented a dark appearance, which on section was found to depend on hæmorrhage in its interior. The substance of the cord was loose and of a somewhat ashy appearance. There was also hæmorrhage in the cord for an inch and a-half above the tumour—this being the extent of the portion sent to Professor Key.

It resulted from the examination that the sarcoma did not arise from the dura mater, but from the adipose tissue surrounding it. Key attributes the paresis and paralysis to the scorbutic hæmorrhages in the spinal cord; and considers that these were not caused by the sarcoma, partly because the new growth must have been of older date than the end of March when the paresis suddenly appeared; partly because the examinations of the spinal cord and its membranes, which he has made in conjunction with Retzius, have shown that the sub-arachnoid space is so capacious that a tumour, of even larger size than the one now described, may exist in the spinal canal

without peculiarly pressing on the cord; finally, because the sarcoma would not produce such a rapid development of the paresis as that which occurred.

MEDICINE.

WIESENER ON A PLUM-STONE IN THE AIR-PASSAGES.—Wiesener related to the Medical Society of Bergen (*Norsk Magazin for Lægevidenskaben*, series iii. vol. iv., abstract in *Nordiskt Medicin. Arkiv*, vol. vi. no. 32) the case of a boy aged five, who in the beginning of September swallowed a plum-stone; immediately afterwards he had cough and vomiting, and appeared well for a quarter of an hour, but was suddenly seized during the day with violent cough and dyspnoea, which lasted an hour. When Wiesener saw him, the same day, there was bronchial fremitus with some dyspnoea; the fremitus was most distinct at the second right costal cartilage; there was loud rhonchus in the remaining parts of both lungs. An emetic was given without relief; and castor-oil was administered. Next day, there was a violent paroxysm of coughing with dyspnoea. Half a plum-stone was found in the evacuations after the castor-oil. There was no obstruction to the passage of an oesophageal sound. For about two months afterwards there were constant dyspnoea, fremitus at the same spot as before, and violent cough, especially at night; the sputa were abundant, frothy, white, later on slightly purulent, and occasionally containing a little blood; coarse rhonchi were heard, especially in the upper lobes. Fever and hectic gradually appeared. Two months after the commencement of the symptoms, he had a more violent paroxysm of cough than before, with hæmoptysis: this was followed by marked improvement and disappearance of the fremitus and rhonchi. Ten days later, he again became worse; the cough became incessant, and the expectoration purulent, often mixed with blood, and foetid. Lying on the right side increased the cough. There was now dulness on percussion in the left infrascapular region; this extended, and was accompanied with coarse râles. After this, the percussion-sound under the left clavicle became tympanic, and the dulness extended to the base of the lung posteriorly, where also was heard a blowing sound, with crackling and mucous rhonchi. The hectic increased. On December 25 he had a violent attack of coughing, during which he ejected a quantity of foetid pus and blood, and a plum-stone, eight lines long and four lines wide. An improvement in all the symptoms quickly followed, and he steadily recovered. There was some contraction of the left side of the chest.

The author believes that the foreign body first lodged in the right bronchus near the bifurcation, and that two months afterwards it passed into the upper lobe of the left lung, causing ulcerative pneumonia, around which pneumonia of reaction was set up. The retraction after the expulsion of the

stone he attributes to the contraction of a cavity. [The reporter in the *Norsk Magazin* suggests that there was empyema.]

A. HENRY, M.D.

SABOURIN ON ATROPHIC SCAPULAR RHEUMATISM AND RHEUMATISMAL MUSCULAR ATROPHY.—Muscular atrophy, a rare complication of rheumatism, shows itself sometimes in the vicinity of the large joints, principally the scapulo-humeral. This atrophy is mostly attributed to rheumatism of the deltoid; but Dr. Sabourin (*Archives Générales de Médecine*, 1874) thinks this very doubtful, and believes that this affection should be called atrophic scapular rheumatism. It is characterised by the following symptoms. The patient, after having been in a cold perspiration, feels pains in his shoulders, which pains, slight at the commencement, increase by degrees. As a rule the joint is neither red nor swollen, and there is no fever. Passive movements of the joint give but little pain, if the patient remain quiescent and do not contract his muscles strongly. The pressure of the articular surfaces against each other does not cause much pain; but spontaneous movements give great pain, and the patient points out as the situation where he feels the pain, not the deltoid, but the outer end of the clavicle, the acromion, and the spine of the scapula, that is to say, the points of insertion of the muscular fibres. The patient may recover, but in the contrary event all movements continue to be painful. Atrophy of the muscles commences and makes persistent progress; it attacks not only the deltoid, but the pectorals, the infraspinatus and supraspinatus muscles, and the other muscles of the scapulo-humeral region to such an extent, that when the patient is undressed there is a great difference in size between the infraspinous and supraspinous fossæ of the two sides. Sometimes the coraco-brachial and biceps muscles are similarly atrophied. With the increase of the atrophy all movements become more and more difficult, and are sometimes quite impossible. Dr. Sabourin has never seen the atrophied muscles regain their normal size and power. Atrophic rheumatism is not peculiar to the scapulo-humeral articulation. When the affection is seated in the knee, the muscles of the thigh, and principally the triceps, become smaller. Atrophic scapular rheumatism may be distinguished from rheumatism of the deltoid by the following characteristics: the pains are seated exclusively at the insertions of the muscles; and in the muscular fasciculi, spots which are painful on pressure in the localities where the fibrous tissue is most superficial; and in the second there is a sensation of fatigue in the muscles which are beginning to atrophy. The disease is not seated in the muscular fibre. Atrophy therefore is produced by the irritative process which, invading successively the tendinous attachments of the muscles, the fibrous envelope, and then the neurilemma of the minute nervous ramifications, of which the nervous element becomes changed, interferes with the nutrition of the muscle. This is, however, but a simple hypothesis of the author which greatly needs confirmation by necropsy,—a means of which he has not availed himself.

FERRAN ON VOMITING OF BLOOD IN HYSTERIA.—M. Louis Ferran's little work on this subject is intended to call attention to symptoms which have hitherto received but little notice. Vomiting of blood by hysterical patients is of frequent

occurrence, and is well described in the numerous cases contained in M. Ferron's book. The author discusses the various explanations hitherto offered of this phenomenon, and offers his own. It is, that hydræmia and plethora have a notable influence, but not sufficient to produce the hæmorrhage. Nearly all the patients observed presented symptoms of chlorosis, so that it appears allowable to assume an incipient cachexia, which first takes effect on the walls of the vessels; and the nervous system, through the medium of the vaso-motor nerves, would play a principal part. These nerves being paralysed, a distension of the vessels would be produced, which, carried too far and exceeding their degree of elasticity and retentibility, would bring on rupture of their tunics. With regard to the differential diagnosis, after having speedily put aside scorbutus, purpura, hæmoptysis, locomotor ataxy and cancer of the stomach, the author finally stops at simple ulcer. Showing the perfect similarity of symptoms existing in the two cases, the author sees that diagnosis is often impossible, but in many cases, however, lays claim to draw from the nature of the pain and the general condition differential signs on which it would be allowable to base an opinion.

UPHAM ON THE TREATMENT OF CEREBRO-SPINAL MENINGITIS.—Dr. J. B. Upham, after a large experience and careful study of the late epidemic in Massachusetts, sums up the indications for treatment as follows, in the *Boston Medical Journal* for September 1874.

Husband the strength; combat the tendency to congestion of the brain and spinal cord; mitigate the intense pain; calm the nervous excitement; nourish and support the system till the exuded morbid products can be removed by the kindly offices of nature. Meantime, minister by all the ways at hand to the comfort and relief of the patient. The choice of means to fulfil these indications is best left to the judgment and good sense of the attending physician.

DOMANSKI ON THE TOPICAL TREATMENT OF DISEASES OF THE LUNGS.—Domanski (*Berliner Clinische Wochenschrift*, January 4, 1875), proposes the inhalation of compressed air charged with medicinal substances in the treatment of bronchitis and of phthisis. He recommends for that purpose oil of turpentine, and also a one per cent. solution of carbolic acid. Such inhalations are always well borne, and do not irritate the larynx. Five patients, who suffered from distressing cough and from copious expectoration, obtained immediate relief under this treatment. Also in one case of phthisis the vital capacity of the lungs is alleged to have increased from 2,850 to 3,100 cubic centimetres, and in another case from 2,100 to 2,300 cubic centimetres.

I. B. BERKART, M.D.

JENNER AND JOHNSON ON CROUP AND DIPHTHERIA.—Sir William Jenner, in a clinical lecture (*Lancet*, January 2 and 16), confesses himself a convert, or almost a convert, to the belief in the identity of croup and diphtheria; he disapproves of the energetic treatment by mercurials and antimony, which is still not unfrequently practised; he recommends tracheotomy, but thinks the hot steamy room and closely curtained bed exhausting to the patient and quite unnecessary. He also describes fully the distinctions between true croup and laryngismus

stridulus, catarrhal laryngitis, and the other kindred affections which occur in childhood.

Dr. George Johnson (*Lancet*, January 2 and 16) also believes in the identity of croup and diphtheria, but he differs from other authorities in thinking that the throat lesion is not an evidence of general disease, but the cause of it; that it is, in fact, analogous to the hard chancre in syphilis, and that consequently the diphtheria can be cured or mitigated by frequent applications to the throat of disinfectant and astringent solutions, as perchloride of iron and chlorinated soda. For the same reason he advises, in laryngeal diphtheria, the spray inhalation of a solution of chlorine or sulphurous acid.

GORE ON THE SLEEPING SICKNESS OF WESTERN AFRICA.—Dr. A. A. Gore, Surgeon-major of the British army, gives, in the *British Medical Journal* for January 2, an account of this curious disease, endemic at some parts of the West Coast of Africa. It begins with swelling of the cervical glands, together with a gradually increasing tendency to sleep; the somnolence becomes more and more constant, until at last the patient cannot even be aroused to take nourishment. The disease lasts from six to twelve months, and is generally fatal. The etiology and pathology are as yet obscure, and the treatment unsatisfactory.

ROUTH ON AN EPIDEMIC OF CONTAGIOUS SORE THROAT.—Dr. Routh describes (*Medical Press and Circular*, January 13) an epidemic of contagious sore throat which occurred in the Cripples' Home. Cases of sore throat and tonsillitis first appeared in this institution in October, 1873, and they continued to occur at intervals until September, 1874, when an epidemic of true scarlet fever broke out; erysipelas was also endemic in the Home during the same period. Dr. Routh seems inclined to believe that the connection between tonsillitis, diphtheria, and scarlet fever is more intimate than it is generally thought to be.

BRUNTON ON KLEIN'S RESEARCHES ON SMALL-POX AND TYPHOID FEVER.—Dr. Lauder Brunton (*Practitioner*, Jan.), thinks that, although we cannot as yet positively assert that the relation of the fungi discovered by Dr. Klein to the intestinal lesion in typhoid fever is that of cause and effect; still this is so exceedingly probable that we may accept it, at least provisionally, as proved, and consider what bearing this new pathology will have upon treatment. Its effect will be, he thinks, to discourage still further all attempts to cut short the disease, when once established, by any therapeutic agents.

PRANGLEY ON DIPHTHERIA.—Mr. T. Prangley (*British Medical Journal*, January 9) gives the experience he has derived from the treatment of fifty-six cases of this disease. He advises the application of tincture of iodine to the throat, and the use of iodised inhalations if the larynx be affected; he orders also a mixture of iron and chlorate of potash, and a liberal amount of food and stimulants.

JOHNSON ON THE TREATMENT OF TYPHOID FEVER.—Dr. George Johnson (*Practitioner*, Jan.), believes strongly in the *vis medicatrix nature* in this disease. He objects especially to acid mixtures and opiates, and thinks a simple milk-diet greatly preferable to the liberal allowance of beef-tea, eggs, etc., which is generally given to typhoid patients.

SURGERY.

LEVIS ON TRANSVERSE FRACTURE OF THE PATELLA.—In the *Philadelphia Medical Times* for December 5, 1874, Dr. Levis asks the question, 'Is fracture of the patella amenable to treatment?' His subsequent remarks evidently refer to the transverse fracture of this bone, which is commonly caused by muscular action. He first mentions the plan of treatment which is said to be followed in the wards of the Hôpital Lariboisière in Paris, that of placing the affected limb on an inclined plane, and keeping it steady by a few turns of a roller, without striving to bring the fragments together; a measure perfectly useless, as, whatever is done, the surgeon can rarely expect anything more than a fibrous union, which, after all, does not interfere with locomotion. What this plan studies to avoid is stiffness of the knee-joint, which frequently follows prolonged immobility of the limb.

To this practice and teaching, those of Dr. Levis are diametrically opposed. In three cases which he selects for illustration, and in which fracture of the patella was left without further treatment than a state of rest to the limb, the separation of the fragments remained far greater than he had seen it as the result of ordinary treatment, in which approximation is effected as thoroughly as is usually practicable. As to the stiffness of the knee following the mechanical treatment, it is due to the synovitis and other inflammation of the surroundings of the fracture rather than to 'prolonged immobility,' which is not during a longer period, nor more thorough, than is necessitated in ordinary cases of fracture of the femur or of the tibia. [And with this statement I may remark in passing that I am inclined to concur.—*Rep.*]

In regard to a 'fibrous union not interfering with locomotion,' he knows from practical experience that a long fibrous union, as is likely to result from such want of treatment, as is the custom at Lariboisière, does interfere with normal locomotion. [This is

a fact, one would have thought, well known to practical surgeons. It was taught by the late Mr. Stanley, and the practice, still apparently in vogue at the Lariboisière, but now generally discontinued throughout this country as having no advantage over the horizontal position of the limb, was originally recommended in the very hope of insuring the better approximation of the fragments, and less of the after-trouble which ensues from loss of power in the extensor muscles of the thigh where the fibrous uniting-band is long—as indeed it commonly becomes from the gradual stretching of the tissue which joins the pieces of the broken patella—such after-trouble consisting in the difficulty which the patient experiences in supporting the body when its balance is suddenly disturbed, and in his liability to fall backwards.—*Rep.*]

After subduing the swelling of arthritis and bursal distension, Dr. Levis always approximates the fragments mechanically as soon as may be practicable. With efficient mechanical treatment he has seen a number of cases in which, if true synostosis was not effected, the fibrous union was so short that no separation was appreciable. [It was not within my knowledge, when recently writing on this subject,* that Dr. Levis had interested himself much respecting it. It will be seen, however, that we express ourselves as to the results of mechanical treatment in words almost identical; and, indeed, the results usually attained are so good that this plan of treatment promises to obtain general acceptance. It must be remembered that the contour of the knee is, with this method of treatment, of some consequence in determining the result, for those cases do best in which the bones which form the joint are sharply outlined, thus giving better holdfasts for the mechanical appliances. The plan which is followed in my wards is, in principle, very like that suggested by Dr. Levis, the chief difference being in the more horizontal traction which is made to bear upon the upper fragments. A description of it is given in the book referred to.—*Rep.*] The following is Dr. Levis's arrangement.

'After some experience with various mechanical contrivances for the treatment of fracture of the patella, I am convinced that the best results, with the most comfort to the patient, can be produced by the simple use of long strips of adhesive plaster and roller-bandages, and with either the limb elevated or the trunk kept raised, so as to flex that portion of the quadriceps muscle which has a pelvic origin. The strip holding down the upper fragment should be long enough to reach spirally down the leg, continuing even to the sole of the foot. In order to render the dressing very secure, several strips of adhesive plaster may be super-imposed so as to give strength and solidity. Strips passing in a contrary direction readily maintain the lower fragment in position, as there is no muscular influence tending to its displacement; and a roller bandage, enveloping the entire limb, completes the dressing.'

In the letter from which this extract is taken, Dr. Levis adds that 'the treatment of fractures in most European hospitals is often careless, unmechanical, and unphysiological. The most favourable exceptions to this condemnation I saw in one or two hospitals in London.' [This sweeping condemnation from so able a surgeon as we know Dr. Levis to be cannot but arrest attention. It may, however, be fairly asserted

* *St. Bartholomew's Hospital Reports*, vol. x. p. 152.

that the results of the treatment of fractures in this country are, as a rule, so satisfactory, that at all events our appliances cannot be deficient in the requirements necessary for practically dealing with the repair of broken bones and for insuring good length and form when, from the situation of the fracture, such details have to be cared for.—*Rep.*]

GEORGE W. CALLENDER.

ANNANDALE ON A NEW FORM OF BOOT FOR THE TREATMENT OF TALIPES EQUINUS.—Mr. T. Annandale, Surgeon to the Royal Infirmary, of Edinburgh, and Lecturer on Clinical Surgery, writes in the *Edinburgh Medical Journal*, January, 1875, as follows. The boot figured was made, at my suggestion, by Mr. Hilliard in September, 1870, in connection with the treatment of a case of talipes equinus. Since then, the appliance has proved so

successful in treating cases of this deformity in my own practice and also in the practice of others, that I recommend it with much confidence to the consideration of my professional brethren.

I have used it under three conditions.

(1) Without any division of the tendo Achillis. If the distortion be not very severe, the application of the boot without any operation is perfectly successful. One interesting case, treated under this head, was that of a little girl, both of whose feet were affected with the deformity. The apparatus was applied to both feet, and resulted in a complete cure.

(2) With division of the tendo Achillis, and, if necessary, the plantar fascia. In aggravated cases, the division of one or both of these structures is usually required; and when the wounds are healed, the application of the boot gradually stretches the contracted ligaments and other textures, and so completes the cure.

(3) With removal of the head of the astragalus in addition to the division of the tendo Achillis. In

one very aggravated case it was found impossible to relieve the deformity, owing to the displacement and projection of the head of the astragalus on the dorsal surface of the foot. I accordingly excised this portion of bone, divided the tendo Achillis, and, when the wounds were healed, applied the apparatus until the deformity was relieved.

A short description of the boot will be sufficient to make its principle understood. It consists, as shown in the illustration, of a footpiece and leg-support, which are connected together by a movable joint at B and C on each side, so as to allow of flexion and extension of the ankle-joint. The essential part of the appliance is the screw A at the back, which is turned by means of a key. When the screw is turned in one direction it elevates the heel, and the appliance can in this way be adapted accurately to the deformed foot. By turning the screw in the opposite direction, the heel is depressed, and the relief of the distortion gradually and efficiently accomplished by acting upon the contracted tendo Achillis and other textures.

The appliance can either be fitted to an ordinary lacing walking boot, or the foot may be secured to the footpiece by a padded strap crossing over the dorsal surface of the foot and ankle. Sometimes I use a lacing-boot of soft leather, similar to that employed in my boot for talipes varus, to secure the foot. In aggravated cases, or in those requiring operation, a combination of the two latter methods is best. The leg is fastened to the leg-support by a broad padded belt passing round the limb at its upper third.

SANTESSON AND ENVALL ON A CYSTIN CALCULUS IN THE FOSSA NAVICULARIS.—The authors describe in the *Hygiea* for 1874 (abstract in *Nordiskt Mediciniskt Arkiv*, vol. vi. no. xxxii.), the case of a man aged thirty-two, who was admitted into the hospital at Karlskrona in May 1870, with retention of urine. During three years he had suffered frequently from the passage of renal calculus; the last and worst attack having occurred a month before his admission. For a fortnight he had difficulty and pain in micturition, and was sensible of the presence of a foreign body in the urethra, which he gradually brought as far as the glans, where it was arrested and entirely obstructed the flow of urine. Without much difficulty Dr. Envall removed from the fossa navicularis a calculus three-fifths of an inch long, about three-tenths of an inch wide, and weighing a little more than nine grains. It was covered with a layer of mucus and urates. On chemical and microscopic examination, it was found to consist of cystin. The urine, which escaped in large quantity after the removal of the calculus, contained a considerable amount of cystin, partly in the form of gravel, partly as a crystalline deposit on evaporation of the urine; and this continued throughout the eight days during which the patient remained in the hospital. He said that his mother and three brothers and sisters were similarly affected; but no further information could be obtained. In commenting on the case, Dr. Santesson remarks that cystin calculi are very rare in Sweden.

WIESENER ON HERNIOTOMY IN A PREGNANT WOMAN—Wiesener (*Norsk Magazin för Lægevidenskaben*) operated on a woman, aged forty, in the ninth month of pregnancy, for an incarcerated crural hernia of the right side. The result was successful.

A. HENRY, M.D.

MAUNDER ON ANEURISM.—Mr. Maunder's first Lettsomian lecture on the diseases of arteries (*Lancet*, January 2 and 16) is on aneurism. It is illustrated by a table showing the results of twenty-seven cases of the ligation of arteries performed by Mr. Maunder, and by reference to numerous interesting cases which have occurred in the practice of the London Hospital. Mr. Maunder speaks highly of the value of compression, especially digital, when it can be carried on with the necessary patience and strict attention to details. In cases of carotid and axillary aneurism, especially, he advises a patient trial of compression before proceeding to ligation, though at the London Hospital ligation of the carotid has been unusually successful (six recoveries out of seven cases). Mr. Maunder approved of the distal operation for aneurism of the innominate artery if medical treatment have failed. In the treatment of aneurisms of the lower limb, compression should not be persevered in too long, as Mr. Holmes's statistics show that this may influence unfavourably the result of a subsequent operation. In the case of popliteal aneurisms, if not too large, flexion should have a fair trial.

BRYANT ON THE LEAST SACRIFICE OF PARTS AS A LEADING PRINCIPLE OF SURGICAL PRACTICE.—In a paper read before the Medical Society of London (*Lancet*, January 23 and 30) Mr. Bryant thinks that the maxim that 'in cases of disease or accident no more of the body is to be taken away than the necessities of the case demand,' is not so generally followed as it should be by surgeons of the present day. He gives numerous examples of his own practice in cases of disease and injury of the hand and foot; and then, applying the same principle to the surgery of the joints, he advocates free incisions and the removal of necrosed bone, if present, instead of formal resection. He relates about twenty cases of advanced disease of the ankle, knee, hip, elbow, and shoulder thus treated successfully, and in most of the cases a movable joint resulted; most of the patients, however, were children.

ANNANDALE ON ANTISEPTIC INCISIONS AS AN AID TO SURGICAL DIAGNOSIS.—Mr. Thomas Annandale (*Edinburgh Medical Journal*, January 1875), advocates the more frequent use of exploratory incisions in the diagnosis of cases of deep-seated abscess, of morbid growths of doubtful nature, and of obscure joint-disease. He says that, by the employment of the antiseptic method, and, where practicable, of Esmarch's bandage, such incisions are perfectly free from risk to the patient, and afford far more certain and valuable information than can be gained by the use of the aspirator, grooved needle, or exploring trocar.

THOMPSON ON OPERATIONS FOR THE RELIEF OF ADVANCED PROSTATIC DISEASE.—Sir Henry Thompson (*Lancet*, January 2), remarks that, in cases of long-standing prostatic disease, the bladder often becomes very irritable; the patient is tormented by an almost constant desire to micturate, and the catheter is in hourly requisition. Under these circumstances, Sir Henry Thompson recommends puncture of the bladder behind the pubes. He gives directions for performing the operation, which, if due precautions are taken, is not, he says, a serious one for the patient.

THOMPSON ON A CASE OF EVERSION OF THE BLADDER.—Dr. George Thompson relates (*Lancet*, January 9), a case of this rare accident occurring in a lady during an attack of acute cystitis. It was caused apparently by the presence of phosphatic deposit. The displacement was readily reduced, and no bad results followed.

OPHTHALMOLOGY AND OTOLOGY.

ROOSA ON DISEASES OF THE INTERNAL EAR.—In a paper in the *American Journal of Medical Sciences* for October, 1874, entitled, 'A Contribution to the Etiology of Diseases of the Internal Ear,' Professor Roosa gives a short *résumé* of some cases which have occurred in his private practice. He finds that 'patients with disease of the internal ear do not usually complain of tinnitus; they usually speak of it as a low murmuring noise, to which they pay very little attention; whereas those who have a tinnitus that is caused by pressure through the fenestræ upon the labyrinth—that is, from disease of the middle or external ear—are usually very much disturbed by it.' He has had some experience among boiler-makers, and says they are nearly all hard of hearing; those who are not, having, as a rule, used a plug of cotton-wool in the external meatus. He attributes the hardness of hearing found in boiler-makers to some lesion of the labyrinth, probably of the cochlea, 'for the chief symptoms are loss of hearing and tinnitus aurium; there is no vertigo or staggering in the gait.' In the cases caused by hæmorrhage into the ear, one would expect that Bright's disease would have played an important part; but Roosa says that in the few cases that have been observed of hæmorrhage into the ear in cases of Bright's disease, the bleeding occurred in the middle, and not in the internal ear. He believes cases of Menière's disease to arise from hæmorrhagic effusion. He doubts that quinine is of itself sufficient to produce disease of the internal or middle ear, but is positive that large doses will aggravate a previously existing aural inflammation, and place it beyond the possibility of cure. He says the tinnitus aurium produced by this drug 'must be due to a congestion of the ultimate fibres of the nerve.' Of sixty-five cases he attributes four to traumatic injury, three to long continued exposure to concussions, eleven to hæmorrhage into the internal ear, two to inflammation of the parotid gland, eight to cerebro-

spinal meningitis, two to scarlatina, one to measles, seven to basilar meningitis, eight to primary inflammation of the labyrinth, four doubtfully to the internal administration of quinine, one to arrested development, and fourteen to unknown causes.

BECKER ON TRANSPLANTATION OF RABBIT'S CONJUNCTIVA INTO THE HUMAN CONJUNCTIVA.—In the *Wiener Medizinische Wochenschrift* for November 14, 1874, Professor Otto Becker, after reviewing shortly the successfully treated cases of Dr. Wolfe, of Glasgow relates two cases of symblepharon on which he has operated in the same way. In the one case, he used a portion of the conjunctiva bulbi of a white rabbit, about eight millimètres square. In the other, in which the loss of substance after loosening the symblepharon was much larger, and he therefore desired a large portion of conjunctiva, he removed the cartilage of the palpebra tertia, and employed the conjunctiva, which covers both sides of that lid. The latter he found more difficult to flatten out well than the conjunctiva from the bulb. He finds that the flap, after removal from the rabbit's eye, is very thin, and has a great tendency to curl, and that, unless notice be taken by marking the branch of the forceps which is applied to the epithelial side, it is difficult to recognise the one surface from the other. He thinks fine needles with very acute angles are necessary for the operation, and recommends those made for him by Luer, of Paris. The transplanted portion remained quiet, not changing its form or colour for the first forty-eight hours, but on the third day vessels could be recognised in it. On the sixth day the suture at the corneal side gave way, and the flap took on a three-sided form; but the result was satisfactory, as the lids were free, the eyeball movable, and the transplanted portion thoroughly engrafted on to the normal conjunctiva, and taking part in its circulation. The foreign tissue was, however, always recognisable by its lighter colour. The other case, on account of the restlessness of the patient, a boy four years of age, was not so successful, but sufficiently so to encourage Professor Becker to recommend the operation. As sutures he uses very fine untwisted silk, which he has used for some time in all conjunctival wounds requiring sutures, and which, he says, do not require to be removed. The suture may suppurate out without causing any complaint from the patient; but it frequently is imbedded in the tissue for years without the patient being aware of its presence.

POLITZER ON THE REMOVAL OF MOVABLE EXUDATION FROM THE TYMPANIC CAVITY.—In the *Wiener Medizinische Wochenschrift* for October 24, Professor Politzer communicates a method of removing exudation from the tympanic cavity. He says that the exudation in the middle ear shows either a purulent character with violent reactionary symptoms, or a serous syrup-like or tenacious slimy character without such symptoms. The exudation exhibiting the former character is much more readily absorbed than the latter, which may lie in the cavity for weeks or months, even when the exudative process which called it into existence has passed away. The mere presence of such a body in the tympanic cavity is sufficient to, and does, cause irritation, hyperæmia, increased secretion, and disturbances of the hearing power. These symptoms may pass on to violent inflammation, with formation of pus and all the unpleasant consequences attending its presence in such a narrow chamber

surrounded with delicate structures. The means which Professor Politzer describes for the removal of such exudations, is the placing of the patient's head forwards and to the opposite side to that from which the exudation has to be removed, so that, the cavity being upwards and the mouth of the Eustachian tube directly downwards, the fluid in the cavity will gravitate to a position directly over the opening of the Eustachian tube; and on the opening of the tube by the air-douche from Politzer's bag, the secretion will, if sufficiently fluid, pass at once into the tube, and so relieve the cavity of its presence. [The reporter uses the same position for the removal of fluid by means of Weber-Liel's elastic catheter, or the usual catheter, the former of which has the advantage of not requiring the passage of the air-douche through the fluid, which is apt to cause its dispersion across the surfaces of the tympanic walls and mastoid cells.—*Rep.*]

MISCELLANY.

CREMATION.—The ministry of the Duchy of Coburg has given permission to the society for cremation in Gotha, to carry its principles into practice; and measures are accordingly being taken to that effect.

PRIZE IN PSYCHOLOGICAL MEDICINE.—Dr. Bonaccossa, of Turin, has presented to the Royal Academy of Medicine in that city a sum of money in the Italian funds, sufficient to produce an annual income of 150 lire (6*l.*), the proceeds to be awarded every fifth year to the author of the best essay on a subject in psychological medicine, to be announced publicly within the first three months of each quinquennial period.

M. PAJOT, who has lectured on obstetrics at the Paris Faculty of Medicine for the last thirty years, lately announced his intention of resigning his chair and retiring into private life. But six hundred of his pupils, warmly seconded by Professor Wurtz, dean of the Faculty, addressed a memorial to him, begging him to reconsider his determination; and M. Pajot, touched by these gratifying evidences of gratitude and sympathy, has consented to resume his course during the ensuing session. The retirement of M. Pajot would indeed be a real loss to the professional staff of the Paris Faculty; only sixty years of age, he is still in the full zenith of his mental powers. He possesses in great perfection the faculty of enchaining the attention of his hearers, and knows well how to enliven the driest details by an apt illustration, a well-timed anecdote, or a witty saying, whilst his thorough earnestness in his endeavour to impart information commands the attentive hearing and respect of his pupils.

THE GERMAN ASSOCIATION OF NATURALISTS AND PHYSICIANS.—Preparations are being made for the next meeting of this association, which will be held at Gratz, the capital of Styria. A committee has been formed of the university professors, with some of the citizens, and the burgomaster of Gratz has been appointed president. The ministry of the interior has made a donation of 10,000 florins (1,000*l.*) towards the expenses; and the provincial committee and the municipality of Gratz have each granted 500*l.*

MARRIAGE AND LONGEVITY.—In his recently published *Study of Sociology*, Mr. Herbert Spencer assails a theory that has long been current with regard to marriage and longevity. That married life is favourable to longevity has generally been regarded as satisfactorily proved by numerous statistics, showing, almost without exception, a greater longevity on the part of the married. When the ratio of deaths in the two classes stand at ten to four and even twenty to four, there would appear to be little room for doubt. But to this astute social scientist the evidence, strong as it seems, furnishes no warrant for the current belief. He regards the case as a substitution of cause for effect. In other words, greater longevity is not the consequence of marriage; on the contrary, marriages are clearly traceable to influences favouring longevity. The principles of natural selection work so strongly in deciding between the benedicts and the bachelors, that the long livers are drawn to the former and short livers to the latter. Marriage, Mr. Spencer holds, is regulated by ability to meet its responsibilities. The qualities which give the advantage here are intellectual and bodily vigour, prudence, and self-control; these, too, are the qualities which determine a prolonged life or a premature death. An even more direct relation is to be found in the instincts which lead most strongly to marriage. The reproductive instincts and emotions are strong in proportion as the surplus vital energy is great, and this in turn implies an organisation likely to last: 'so that, in fact, the superiority of physique, which is accompanied by strength of the instincts and emotions causing marriage, is a superiority of physique also conducive to longevity.' Another influence tells in the same direction. Marriage is determined by the preference of women as well as the desires of men, and other things being equal, women are attracted towards men of physical and intellectual power, refusing the malformed, diseased, and ill-developed types. In the operation of these three elements Mr. Spencer finds all that is needed to account for the striking difference of longevity between the classes, and declares that 'the figures given afford no proof that marriage and longevity are cause and consequence; but they simply verify the inference which might be drawn *à priori*, that marriage and longevity are concomitant results of the same cause.'

THE PHYSIOLOGY OF VERSIFICATION.—A curious and interesting paper by Dr. Oliver Wendell Holmes, published in the *Boston Medical and Surgical Journal* for January, 1875, is intended to prove that respiration has an intimate relation with the structure of metrical compositions. He tells us that in his opinion the fact that the form of verse is conditioned by economy of those muscular movements which ensure the oxygenation of the blood, is one on which many have acted without knowing why they did so. He first considers the natural rate of respiration. Of 1,817 individuals who were the subject of Mr. Hutchinson's observations, 'the great majority (1,731) breathed from sixteen to twenty-four times per minute. Nearly a third breathed twenty times per minute, a number which may be taken as the average' (Flint's *Physiology*, vol. i. p. 392). He continues, 'The "fatal facility," of the octosyllabic measure has often been spoken of, without any reference to its real cause. The reason why eight syllable verse is so singularly easy to read aloud is that it follows more exactly than any other measure the natural rhythm of respiration. In reading aloud in the ordinary way from *The Lay of the Last Minstrel*, from *In Memoriam*, or from *Hiawatha*, all written in this measure, the first two in iambs, or short-

longs, the last in trochaics or long-shorts, it will be found that not less than sixteen nor more than twenty-four lines will be spoken in a minute, probably about twenty. It is plain, therefore, that if one reads twenty lines in a minute; and naturally breathes the same number of times during that minute, he will pronounce one line to each expiration, taking advantage of the pause at its close for inspiration. The only effort required is that of vocalising and articulating; the breathing takes care of itself, not even demanding a thought except where the sense may require a pause in the middle of a line. The very fault found with these octosyllabic lines is that they slip away too fluently, and run easily into a monotonous sing-song. In speaking the ten syllable or heroic line, that of Pope's *Homer*, it will be found that about fourteen lines will be pronounced in the minute. If a breath is allowed to each line the respiration will be longer and slower than natural, and a sense of effort and fatigue will soon be the consequence. It will be remembered, however, that the cæura, or pause in the course of the line, comes in at irregular intervals as a 'breathing-place,' which term is its definition when applied to music. This gives a degree of relief, but its management requires care in reading, and it entirely breaks up the natural rhythm of breathing. The fourteen syllable verse, that of Chapman's *Homer*, the common metre of our hymn-books, is broken in reading into alternate lines of eight and six syllables. This also is exceedingly easy reading, allowing a line to each expiration, and giving time for a little longer rest than usual at the close of the six syllable line. The twelve syllable line, that of Drayton's *Polyolbion*, is almost intolerable, from its essentially unphysiological construction. One can read the ten syllable line in a single expiration without any considerable effort. One instinctively divides the fourteen syllable line so as to accommodate it to the respiratory rhythm. But the twelve syllable line is too much for one expiration and not enough for two. For this reason, doubtless, it has been instinctively avoided by almost all writers in every period of our literature. The long measure of Tennyson's *Maud* has lines of a length varying from fourteen to seventeen syllables, which are irregularly divided in reading for the respiratory pause. Where the sense does not require a break at some point of the line we divide it by accents, three in each half, no matter what the number of syllables; but the breaks which the sense requires so interfere with the regularity of the breathing as to make these parts of *Maud* among the most difficult verses to read aloud, almost as difficult as the *Polyolbion*.'

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 1*7s.* 4*d.*; free by post, 1*9s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 1*9s.* 6*d.* Cloth Cases for binding the Numbers for each year may be had for 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

WEDNESDAY, FEBRUARY 17, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON ALCOHOL. By B. W. RICHARDSON,
M.D., F.R.S.*

(Concluded from page 78.)

Does Alcohol increase the Animal Heat?—In putting before you this inquiry, I am prepared to answer it by direct knowledge gained from individual experiment. In the course of some researches I had to make for reports rendered to the British Association for the Advancement of Science, it became part of my duty to ascertain what effect certain chemical agents exert over the animal temperature. Amongst these agents was alcohol.

At the time when my researches commenced, viz., in the year 1864, there was nothing definitely known on the subject. The thermometer was not then in such general use as it is now, and it had not been applied, as far as I know, to this particular determination. Generally, however, it had been assumed by the majority of persons that alcohol warms the body, and to 'take just a drop to keep out the cold' had been the practice which the experience of ages seemed to justify. It is fair, at the same time, to say that Dr. Lees, and some other far-seeing observers, had for many years held and asserted a different view. They had not entered into minuteness of experimental detail, but they had observed from the effects of alcohol on those who had been exposed to cold in the extreme north and in other regions of ice and snow, that the drinkers did not live on like other men. Thus, in so far as I had what is called experience to guide me, I found conflict of opinion. It was not my business, however, to accept guidance of this kind, but to appeal to the only safe guide, the direct interrogation of nature by experiment.

It were impossible for me to recount the details of the long research—extending, with intervals of rest, for three years—which was conducted in my laboratory, to determine the influence of alcohol on the animal temperature. The effects were observed on warm-blooded animals of different kinds, including birds; on the human subject in health, and on the same subject under alcoholic disease. Similar experiments were made in different external temperatures of the air, ranging from summer heat to ten degrees below freezing-point. The whole were carried on from experiment to experiment, without regard either to comparison or result, until the general character of result began to proclaim that a rule existed which could hardly be considered exceptional. The facts obtained I may epitomise as follows.

The progressive stages of change of animal function from alcohol are four in number. The first is a stage of excitement, when there exists that relaxation

and injection of the blood-vessels of the minute circulation with which we have become conversant. The second is the stage of excitement, with some muscular inability and deficient automatic control. The third is a stage of rambling, incoherent, emotional excitement, with loss of voluntary muscular power, and ending in helpless unconsciousness. The fourth and final stage is that in which the heart itself begins to fail, and in which death in extreme instances of intoxication closes the scene. These stages are developed in all the warm-blooded animals, and the changes of temperature throughout the whole are relatively the same.

In the first stage, the external temperature of the body is raised. In birds—pigeons—the rise may amount to a full degree, on Fahrenheit's scale; in mammals it rarely exceeds half a degree. In man it may rise to half a degree, and in the confirmed inebriate, in whom the cutaneous vessels are readily engorged, I have seen it run up to a degree and a half. In this stage, the effect on the extremities of the nerves is that of a warm glow, like what is experienced during the reaction from cold.

The heat felt in this stage might be considered as due to the combustion of the alcohol; it is not so; it is in truth a process of cooling. It is from the unfolding of the larger sheet of the warm blood and from the quicker radiation of heat from that larger surface. During this stage, which is comparatively brief, the internal temperature is declining; the expired air from the lungs is indicating, not an increase, but the first period of reduction in the amount of carbonic acid, and the reddened surface of the body is so reduced in tonicity that cold applied to it increases the suffusion. It is this most deceptive stage that led the older observers into the error that alcohol warms the body.

In the second stage, the temperature first comes down to its natural standard, and then declines below what is natural. The fall is not considerable. In birds it reaches from one and a half to two degrees. In other animals, dogs and guinea-pigs, it rarely exceeds one degree; in man it is confined to three-fourths of a degree. In a room at a temperature of 65° or 70° the decrease of temperature may not actually be detected, but it is quickly detected if the person in whom it is present pass into a colder atmosphere, and it lasts, even when the further supply of alcohol is cut off, for a long period, viz., from two and a half to three hours. It is much prolonged by absence of food.

During the third degree the fall of temperature rapidly increases, and as the fourth stage is approached it reaches a decline that becomes actually dangerous. In birds the reduction may be five degrees and a half, and in other animals three. In man it is often from two and a half to three degrees. There is always during this stage a profound sleep or coma, and while this lasts the temperature continues reduced.

It is here worthy of incidental notice that, as a rule, the sleep of apoplexy and the sleep of drunkenness may be distinguished by a marked difference in respect to temperature. In apoplexy the temperature of the body is above, in drunkenness below, the natural standard of 98° of Fahrenheit's scale.

Under favourable circumstances, a long period is required before the body recovers its natural warmth after such reduction of heat as follows the extreme stage of alcoholic intoxication. With the first conscious movements of recovery there is a faint rise,

* Cantor Lecture, No. IV. *Journal of the Society of Arts.*

but such is the depression, that these very movements exhaust and lead to a further reduction. I have known as long a period as three days required, in man, to bring back a steady natural return of the full animal warmth.

Through every stage, then, of the action of alcohol—barring that first stage of excitement—I found a reduction of animal heat to be the special action of the poison. To make the research more perfectly reliable, I combined the action of alcohol with that of cold. A warm-blooded animal, insensibly asleep in the third stage of alcoholic narcotism, was placed in a chamber—the air of which was reduced in temperature to ten degrees below freezing-point—together with another similar animal which had received no alcohol. They both sleep under these circumstances, but the alcoholic sleeps to die; the other simply sleeps more deeply than is natural, sleeps and lives so long as the store of food with which it is charged continues to support life. Within this bound it awakes in a warmer air, uninjured, though the degree of cold be carried even to the act of freezing of the extreme parts.

One more portion of evidence completes the research on the influence of alcohol on the animal temperature. As there is a decrease of temperature from alcohol, so there is proportionately a decrease in the amount of the natural product of the combustion of the body. The quantity of carbonic acid exhaled by the breath is proportionately diminished with the decline of the animal heat. In the extreme stage of alcoholic insensibility—short of the actually dangerous—the amount of carbonic acid exhaled by the animal and given off into the chamber I constructed for the purposes of observations was reduced to one-third below the natural standard. On the human subject in this stage of insensibility, the quantity of carbonic acid exhaled has not been measured. But in the earlier stage of alcoholic derangement of function, the exhaled gas was measured with much care by another earnest worker, whose recent death we have also to deplore, Dr. Edward Smith. In these early stages, Dr. Smith found that the amount of carbonic acid was reduced in man, as I have found it in the lower animals, so that the fact of the general reduction may be considered as established beyond dispute.

We are landed then at last on this basis of knowledge. An agent that will burn and give forth heat and product of combustion outside the body, and which is obviously decomposed within the body, reduces the animal temperature, and prevents the yield of so much product of combustion as is actually natural to the organic life.

What is the inference? The inference is that the alcohol is not burned after the manner of a food which supports animal combustion; but that it is decomposed into secondary products, by oxidation, at the expense of the oxygen which ought to be applied for the natural heating of the body.

For some time to come the physiological world will be studiously intent on the discovery of the mode by which alcohol is removed from the organism. It is a subject on which I shall one day be able to speak, I hope, with some degree of experimental certainty, but on which at this moment I am not prepared to offer more than an indication of the probable course of research. I may venture to add, in advance, two or three suggestions to which my researches, as far as they go, point.

Firstly, I believe there is a certain determinable

degree of saturation of the blood with alcohol, within which degree all the alcohol is disposed of by its decomposition. Beyond that degree the oxidation is arrested, and then there is an accumulation of alcohol, with avoidance of it, in the unchanged state, in the secretions.

Secondly, the change of decomposition of the alcohol in its course through the minute circulation, in which it is transformed, is not into carbonic acid and water, as though it were burned, but into a new soluble chemical substance, probably aldehyde, which returns by the veins into the great channels of the circulation.

Thirdly, I think I have made out that there is an outlet for the alcohol, or for the fluid product of its decomposition into the alimentary canal, through the secretion of the liver. Thrown into the canal it is, I believe, subjected there to further oxidation, is in fact oxidised by a process of fermentation attended with the active development of gaseous substances. From this surface the acid product is in turn re-absorbed in great part and carried into the circulation, and is disposed of by combination with bases or by further oxidation.

Here, however, I leave the theoretical point to revert to the practical; and the practical is this, that alcohol cannot, by any ingenuity of excuse for it, be classified amongst the foods of man. It neither supplies matter for construction nor for heat. On the contrary, it injures construction and it reduces temperature.

Effect on Muscular Power.—Behind the question of the effect of alcohol upon the animal temperature, was another subject for inquiry. It was fair to ask whether, if heat were not produced by it, some additional stimulus might be communicated by the spirit to the muscular fibre. There is nothing in what we see relating to the action of alcohol in man that would lead us to suppose it capable of giving an increased muscular power, and it is certain that animals subjected even for short periods of time to its influences lose their power for work in a marked degree. Indeed, if we were to treat our domestic animals with this agent in the same manner that we treat ourselves, we should soon have none that were tameable, none that were workable, and none that were edible. I thought it, nevertheless, worth the inquiry whether at any stage of the alcoholic excitement living muscle could be induced to show an extra amount of power; I therefore submitted muscle to this test. I gently weighted the hinder limb of a frog until the power of contraction was just overcome; then by a measured electrical current I stimulated the muscle to extra contraction, and determined the increase of weight that could thus be lifted. This decided upon in the healthy animal, the trial was repeated some days later on the same animal after it had received alcohol in sufficient quantity to induce the various stages of alcoholic modification of function. The result was that through every stage the response to the electrical current was enfeebled, and, so soon as narcotism was developed by the spirit, it was so enfeebled that less than half the weight that could be lifted in the previous trial by the natural effort of the animal could not now even be raised under the electrical excitation.

In man and in animals, during the period between the first and third stages of alcoholic disturbance, there is often muscular excitement, which passes for increased muscular power. The muscles are then

truly more rapidly stimulated into motion by the nervous tumult, but the muscular power is actually enfeebled.

Hygienic Considerations.—The facts I have endeavoured to lay before you will suggest to your minds many thoughts bearing upon the health of individuals and communities, in so far as health is affected by the potent agent, alcohol. I need hardly, indeed, presume to offer any suggestions, but one or two of a specially practical and everyday character may be ventured.

I am bound to intimate that the popular idea of administering alcohol for the purpose of sustaining the animal warmth is an entire and dangerous error, and that, when it is brought into practice during extremely cold weather, it is calculated to lead even to fatal consequences, from the readiness with which it permits the blood to become congested in the vital organs. I cannot too forcibly impress the fact that cold and alcohol act, physiologically, in the same manner, and that, combined in action, every danger resulting from either agent is doubled.

Whenever we see a person disposed to meet the effects of cold by strong drink, it is our duty to endeavour to check that effort; and whenever we see an unfortunate person under the influence of alcohol, it is our duty to suggest warmth as the best means for his recovery. These facts prompt many other useful ideas of detail, in our common life. If, for instance, our police were taught the simple art of taking the animal temperature of those persons whom they find in the streets in a state of insensibility, the result would be most beneficial. The operation is one that hundreds of nurses now carry out daily, and, applied by our police-officers, it would enable them not only to detect the difference between a man in an apoplectic fit and a man intoxicated, but would suggest naturally the instant abolition of the barbarous practice of thrusting the really intoxicated into a cold and damp cell, which to such a one is actually an anteroom to the grave.

Once more: I would earnestly impress that the systematic administration of alcohol for the purpose of giving and sustaining strength is an entire delusion. I am not going to say that occasions do not arise when an enfeebled or fainting heart is temporarily relieved by the relaxation of the vessels which alcohol, on its diffusion through the blood, induces; but that this spirit gives any persistent increase of power by which men are enabled to perform more persistent work is a mistake as serious as it is universal.

Again, the belief that alcohol may be used with advantage to fatten the body is, when it is acted upon, fraught with danger. For if we could successfully fatten the body, we should but destroy it the more swiftly and surely; and as the fattening which follows the use of alcohol is not confined to the external development of fat, but extends to a degeneration through the minute structures of the vital organs, including the heart itself, the danger is painfully apparent.

In conclusion, whatever good can come from alcohol, or whatever evil, is all included in that primary physiological and luxurious action of the agent upon the nervous supply of the circulation to which I have endeavoured earnestly to direct your minds. If it be really a luxury for the heart to be lifted up by alcohol; for the blood to course more swiftly through the brain; for the thoughts to flow more vehemently; for words to come more fluently; for emotions to rise ecstatically, and for life to rush

on beyond the rate set by nature, then those who desire the luxury must enjoy it—with the consequences.

OERTEL ON THE TREATMENT OF DIPHTHERIA.*

(Continued from page 81.)

In contrast to these various methods of limiting the further progress of diphtheria by antiphlogistic, caustic, astringent, and similar means, the intent of which is to combat the inflammatory reaction of the mucous membrane caused by the fungi, is the effort which has been made to excite energetically a rapid and abundant production of pus. I endeavoured to solve this problem by the employment of moist warmth, in the form of hot vapour, by means of which a temperature of from 113° to 122° Fahr. was kept up for a considerable time in the mouth of the patient, and I could at once determine the appearances of reaction due to the attempt; viz., an abundant suppuration, causing demarcation.

The first appearances which are observed as a result of the operation of hot vapour are always constant, and distinctly noticeable as early as at the end of from twelve to eighteen hours, during which the inhalation has been practised hourly or half-hourly for a quarter of an hour at a time; but these effects will be developed more slowly if a considerable fibrinous exudation, with partial decomposition of the pseudo-membranes, have already taken place, and the capacity for reaction of the tissues be almost extinguished; or they will not be induced at all where the process has already run into septicæmia. The margins of the diphtheritic deposits, which generally pass imperceptibly into the surrounding tissues, become more sharply defined, and contrast strikingly with the intensely reddened mucous membrane. The membranes, therefore, at the first glance seem enlarged. In some places, too, it will appear as if new membranes had formed where before there had been none. This is due to the fact that they had previously escaped notice from their small size, and from the presence of mucus, which concealed their outlines. Thus it will appear as if the disease had increased in intensity. The operation of the hot vapour, however, has been to induce a considerable excretion of pus-corpuscles, and these have infiltrated the epithelium, or its delicate network, which was already infected and grown full of micrococci. Under longer continued operation of the hot steam, soon no further enlargement of the patches will be noticed. The pseudo-membranes become gradually thicker, and are raised up from the mucous membrane; their whitish-gray colour becomes more yellowish or of a dirty grey, and their surfaces wrinkled and uneven, while the redness of the adjacent mucous membrane also fades and the swelling disappears. After some days we obtain with the necessary amount of suppuration a complete detachment of the pseudo-membranes, and they are expectorated by the patient, either whole, or in single scarcely noticeable fragments, or are possibly in part swallowed. The thickness of such membranes, as a rule, never amounts to less than $\frac{1}{16}$ of an inch.

In the application of the hot vapour an ordinary broad pot, with boiling water or infusion of mallows, can be used, from which the vapour as it forms is conducted through a suitable funnel, as hot and abundant as possible, into the mouth of the patient;

* *Ziemssen's Cyclopædia.*

or, if we prefer it, we may use an apparatus which is expressly made for such purposes. This apparatus, which I have used for several years, wonderfully facilitates the employment of hot vapour, especially with children. The wide conducting-tube is simply placed in front of the open mouth, or is allowed to be taken into the mouth itself, and an uniform development and introduction of the hot vapour is thus secured. With this apparatus we can at the same time accomplish a thorough cleansing of the cavity of the mouth and throat from mucus and the fluids of the mouth, by employing a fluid which dissolves the mucus, but which at the same time acts indifferently on the organism. Such a fluid, steadily flowing over the mucous membrane, washes away masses of mucus, remnants of food, and other products of decomposition. We can also use suitable weak solutions of chloride of sodium, or chlorate of potash or other alkalies; only we must avoid strong disinfecting substances, such as carbolic acid or permanganate of potash, because after long-continued inhalation, more or less of these substances is always carried into the bronchi, and may produce symptoms of irritation.

Solutions of common salt or chlorate of potash, if this latter be preferred, of the strength of from ten to fifteen grains to the ounce, produce no injurious effect upon the organism; that is, they act perfectly indifferently when so used; and a long series of forced experiments, such as are not usually carried out in practice, never resulted in an affection of the bronchi or of the lungs. How long these operations should last, and how often they should be repeated, must be determined by the degree of the affection; and it should not be forgotten that the shorter we make the sittings and the longer the intervals, so much the more slow and uncertain we find the reaction, while the disease thereby gains in intensity and extent. If, therefore, we aim at producing a rapid and free suppuration, the inhalations must be practised as often and as long as possible, in quarter-hour sittings every half hour, and on the first and second day three or at the utmost four hours of sleep must suffice for the patient, while nourishment must be supplied in small portions in the intervals between the separate sittings. Later on, when the pseudo-membranes have been partially cast off, as well as in certain lighter cases, hourly sittings of about a quarter of an hour's duration suffice, and a longer time, six or eight hours, can be allowed for the night's rest of the patient. Even when a complete separation of the membranes has taken place, so long as a secretion of pus is still perceived at the diseased places on the surface of the mucous membrane, occasional inhalations should still be practised every two or three hours, and these are also finally to be suspended after the cleansing of the mouth and throat is complete. By employing the atomising apparatus, a cleansing of the mouth and throat can also be combined with the inhalations. If a simpler mechanism be employed, these cavities will have to be kept clear of the accumulated masses by industrious washing and syringing. Disinfection and destruction of the micrococcus growths, of the products of infection and decomposition, will not, of course, be attained thereby.

Prevention of Septic Disease and General Systemic Poisoning.—We possess no method of completely disinfecting the diseased organs. It follows from our investigations into the treatment of the local inflammation, that it is impossible to annihilate the

diphtheritic contagious material completely by mechanical removal of the deposits from the mouth and throat, or by destruction of them with caustics. Another way in which the objections inherent in these methods may be overcome is one which has long been a favourite in therapeutics; viz., to destroy, by industrious gargling and rinsing of the diseased cavities, the septic ferments and the substances which have entered upon decomposition and are acting as poisons. A glance at the history of diphtheria and its treatment shows that attempts of this kind have at no time been wanting. The most usual remedies for counteracting, as far as may be, the fungous growths and the progressive decomposition, and for limiting their entrance into the tissues and their absorption, are, first, spirits of wine and diluted chlorine-water, in the proportion of one to three; in the next place, solutions of carbolic acid or permanganate of potash, one or two grains to the ounce; besides these medicaments, solutions of hypochlorite of soda, forty grains to the ounce, and of hyposulphite of soda, twenty-two grains to the ounce, and the crude flowers of sulphur, are also esteemed for the same object.

The most suitable remedies, then, to meet the indication of opposing septic infection and general poisoning of the system successfully are, on the basis of experimental investigation, alcohol, freshly prepared and properly diluted chlorine-water (containing fifteen to thirty per cent. of chlorine-water), solutions of permanganate of potash, one and a half to two and a half grains to the ounce, and of carbolic acid, two and a half grains to the ounce, or where this cannot be borne, a like solution of oil of thyme in equal parts of spirits of wine and water. Since these substances, on account of their concentration, are not suited for inhalation, in which a certain portion is always liable to reach the lungs and occasion symptoms of irritation, they will most judiciously be used as gargles. With these the patient has to rinse his mouth once or twice at least every hour, or where this is not easily possible, as in the case of small children, we must seek to cleanse the mouth and throat by the use of the syringe.

But, rational and promising as this antiseptic and disinfecting method appears, still we must never lose sight of two points; viz., that by these means no limits are set to the inflammation and exudation on the mucous membranes; on the contrary, possibly even an increase of these may be induced; then, in the second place, that owing to the fact that these fluids only occasionally bathe the mouth and throat, a complete destruction of the masses of micrococcus cannot be effected, for they grow not only in the thick brawn-like deposits, but they may have already gained entrance into the tissues of the mucous membrane and into the serous canaliculi and lymphatic vessels. We cannot then procure a complete destruction of these parasites by any one of the gargles which have hitherto been available, unless we are willing at the same time to cauterise destructively both the healthy and the diseased mucous membrane, with all the results already detailed.

Empirical knowledge, gained by practice in the treatment of diphtheria with antiseptic gargles for years past, quite agrees with these results, and the various specific remedies of this kind have in no way stood the test of experience.

There is a possibility that the organism may

limit and even prevent septic disease and a general infection, through the capacity for reaction which belongs to the affected tissues. This is also the way in which nature herself affects a cure. I have repeatedly called attention to these facts, which I have observed during several years past; and Professor Eberth, in Zürich, has expressed a similar opinion in regard to the healing of diphtheritic wounds.

In the case of the mucous membrane deprived of its epithelium, and covered with fungous growths and inflammatory exudation, if a due reaction set in, and the cell-formation be active, as in a diphtheritic wound, the micrococci are washed away with the pus; or in case a thick layer of fungus has already been formed, this will be removed by a suppurative process of demarcation. Inversely, in case of slight reaction of the tissue, with rapid increase of the parasites, the suppuration which ultimately sets in will no longer suffice to check the further advance of the fungi and septic materials; that is, to prevent the local and general infection. Finally, certain individual differences in the capacity of reaction of the tissues are also severally liable to favour or retard these processes; and this very difference, to which we would call special attention, must also take a part in those cases in which the fungus cannot be regarded as the only cause of suppuration.

To set up a rapid and abundant suppuration will then form one of the first indications of our present task; and with this we should always combine the use of antiseptic gargles, to secure the utmost possible cleansing and disinfection of the cavities involved. By the energetic use of hot vapour this demand will be met agreeably to nature, at the same time that the separation of the pseudo-membranes is hastened by it; the micrococci are partly taken up by the rapidly forming pus-corpuscles, and partly washed away by them, and an impermeable layer is opposed to the septic masses, until finally the false membranous layer becomes completely detached from the rapidly regenerating tissue of the mucous membrane. According to the individual peculiarity in capacity of reaction, will this separation occur more or less rapidly; and it will depend upon the height the disease has already reached, whether the septic affection and general poisoning can be prevented, and how far this can be done.

The mode in which the hot vapour is to be employed to meet this indication will be the same as that which was found suitable in combating the local inflammation. The number and duration of the separate inhalations will be arranged in accordance with the intensity and extent of the local process, since the elimination of the fungi and septic materials follows at once upon the casting-off of the membranes. The longer the disease has already lasted, the greater the extent of the exudation and the more rapid its decomposition, so much the more energetically must the use of the vapour be pushed, the highest possible temperature being used, and the quarter-hour sittings following each other at intervals of half an hour. At the same time, the mouth and throat must be carefully gargled or syringed out every hour with diluted alcohol or solutions of carbolic acid and permanganate of potash, two and a half grains to the ounce.

Now, although the principles of the local treatment of diphtheria, as determined by pathological and physiological considerations, also generally serve

as our guide in the affections of adjacent organs, still certain modifications must enter into this treatment if the diphtheritic process have occasioned a pseudo-membranous exudation on the mucous membrane of the nasal cavity, the larynx, the trachea, and the bronchi.

BRAXTON HICKS ON RULES FOR THE ADMINISTRATION OF ERGOT.

Dr. J. Braxton Hicks, in a lecture published in *Guy's Hospital Gazette*, February 6, 1875, says, There is a rule which I may as well mention here, namely, *not to give secale if any obstacle to delivery is expected, unless we are prepared to render assistance when the pains have been roused*. I have seen the former portion of this rule enforced, but this is limiting our use of secale too much. Unless we have instruments, etc., close by, then the rule holds good. As an instance of the employment of this drug under these circumstances, I may mention a case. I was sent for in consultation to a patient who had been a long time in labour. The pains had subsided. Two doses of liquor secalis had been given, but without any result. The uterus was still motionless. It was not in a permanently contracted condition. I therefore repeated a third dose. I waited an hour without result. Thinking that perhaps the preparation was at fault I gave twenty grains of the powder, boiled in water, and drunk with the dregs. In a quarter of an hour the uterus was in full action. We had suspected some obstruction from noticing the size of the pelvis. I was therefore ready with the forceps. After waiting fairly and finding no advance, the forceps was applied and the child delivered, an active uterus making the remainder of delivery safe and natural. The same would occur in a very contracted pelvis; if the uterus should fail in its activity in this case, even if we perforate first (supposing we do not think it advisable to turn) we are much assisted, and no danger is run, if we arouse the uterus into action before we draw down the child. It is difficult to lay down rules as to when it is urgent, in cases of inactivity of the uterus, that we should stir it up to action. I remember, in my younger days, allowing the head of a premature foetus to rest on the perinaeum for twelve hours, at the end of which time there was one pain and the child was expelled. The administering of a dose of secale would at any time rouse 'pains'; still, as there was no pressure, and as no ill resulted, there was no necessity. The pulse remaining good, and no aberration from the normal state existing, we may elect to wait without serious harm; it may be more convenient to get the labour over, and we shall not be acting wrong in hastening matters. But when the pulse rises, feverishness begins, and the patient becomes anxious, fretful, and irritable, it is as well, the path for the exit of the child being clear, to give a dose of secale, especially if we have tried the perhaps milder though less certain measures at our hand for stirring up 'pains.' When the case is well selected, the full dose of secale, from half a drachm to one drachm, acts more satisfactorily than an expellent than small frequent doses. The latter tend to irritate the uterus and retain the child. If the uterus, however, be violently roused to expulsion, while the passages are unprepared or obstructed, then the uterus may injure and rupture itself, or may tear down the obstacle, rending the vagina or perinaeum, or damage the child by pressure; or crush its cranial

bones, or rupture the longitudinal sinus by too much overlapping.

I prefer to give ergot in the form of powder, twenty to thirty, or even forty grains boiled in water, and the whole taken; this may be repeated in twenty or thirty minutes. There are many preparations, which can be given if proved to be good, in the equivalent doses. The ethereal tincture keeps well and is efficient, but is nauseous and liable to cause vomiting. It is prompt, and may be useful in *post partum* hæmorrhage. Ergotine has been employed in about four-grain doses injected subcutaneously. It is said to be very efficient and rapid in action, but personally I have not sufficient experience of it at present to speak of it more. It will be a very great advantage if ergot can be made to act promptly. Given in the form of a powder it is slow, even when previously boiled. It is more efficient if we employ the liquor or tincture, still it is then very slow for such cases as *post partum* floodings. In ten minutes the crisis has often passed with one of two terminations; thus, although *secale* is good in the milder cases of flooding, it is practically useless in the sudden forms, unless its action come in afterwards, when our more active treatment has succeeded, to secure permanent contraction. It is a questionable point whether large doses of *secale* do not depress the heart's action, so much as to render its employment to be avoided in extreme cases of flooding. I am inclined to think that it has this effect; but this will not affect our employing it in cases without violent flooding. If in cases of flooding before labour we want to increase uterine action, we may generally employ it, unless the patient be nearly pulseless. It is always a great comfort to feel that when the child is born, the uterus will most probably be in an active state from the previous dose of ergot.

It has also been supposed that ergot is poisonous to the child. For myself, I have no proof of its poisonous properties, but I have often seen it kill the child. If you give it in ill-suited cases—I mean where the uterus, as in many primiparæ, is already irritated, where it has already half-asphyxiated the child, by pressing on the funis, placenta, and half closing the sinuses, then a dose of *secale* will go far to ensure its death; or if impaction be already present, and the suture overlapping, then the parts inside the cranium are pressed upon so hard as to extinguish life, or at least so to damage the brain as to make the child an intellectual wreck. Given in moderate doses, and in true inertia, I know no drug which is so certain of producing the desired effect.

MEDICINE.

BRUNTON ON COTTON-WOOL IN THE EARS AS A PROPHYLACTIC AND CURATIVE APPLICATION IN CORYZA AND SORE THROAT.—A correspondent informs us (*Practitioner*, February, 1875) that colds in the head or sore throat may frequently be prevented by placing cotton-wool in the ears when an attack is feared. Even when the attack has commenced, it may be cut short by the same simple application. If one side of the nose or throat only be affected, it is sufficient to place cotton-wool in the corresponding ear. In some cases it is unnecessary to do more than plug the orifice of the auditory meatus, but in others having delicate ears it is advisable to cover part of the concha as well. The beneficial effects of the application are

most marked in those who have a large meatus or a thin and delicate ear, and are less distinct when the meatus is small or the ear large and thick.

A little consideration will show that this proposal is by no means unlikely to be of practical use, and at the same time to throw some light on the causation of internal inflammations. Inflammation of any part of the body is sometimes produced by irritation in another part closely connected with the first by means of the nervous system. In the case of the ear it is easy to see how an irritant applied to it may lead to sore throat. Brücke mentions in his *Physiologie*, and anyone can readily verify his statement, that if a paper spill be pushed well into the auditory meatus, and moved about, a feeling of tickling will be felt in the throat, and if the irritation be continued coughing will ensue. The reason of this is, that the vagus nerve gives off one branch (the ramus auricularis) to the ear, and another branch (the superior laryngeal) to the larynx, as well as branches to the pharynx. When the ramus auricularis is irritated by the paper spill, the irritation is not rightly localised by the nerve-centres, but is felt as if it had been applied to the laryngeal and pharyngeal branches of the same nerve.* And, if irritation of the auricular nerve by a paper spill thus causes a sensation exactly resembling the effect of irritation applied to the part supplied by the laryngeal and pharyngeal nerves, it seems by no means improbable that a continuous irritation applied to it by a draught of cold air may actually cause inflammation in the pharynx, while its protection by cotton-wool in the meatus may prevent any such consequences, in somewhat the same way as a covering over a horse's loins greatly lessens the risk of nephritis. The renewed application of the same irritant which has produced the inflammation may, and probably does, tend to keep it up. The cotton-wool, by preventing this renewal, may exert a curative as well as a prophylactic action. The effects of cotton-wool on cold in the head are more marked than upon sore throat; but it is not quite so easy to show the nervous communication between the ear and the nose as between the ear and the pharynx.

It is not unfrequently observed that cold is more readily caught from a draught playing on the side or back of the head, than from one meeting us fairly in the face and blowing directly down our throat; and these observations on the nervous connections between the ear and the throat may help us to understand the cause of this, and suggest to us the propriety of delicate persons carefully protecting the sides of the head as well as of wearing a comforter.

It must be borne in mind that strumous children, who are liable to colds, often suffer from discharges from the ear; and care must be taken that cotton-wool is not recommended indiscriminately and applied carelessly, as it might lead to the discharges accumulating in the meatus and doing mischief.

Colds in the head and throat are so common and troublesome, and the remedy is so simple, that it well seems to deserve a trial. Our correspondent is specially subject to colds of an unusually severe and oppressive character, yet he has, by the use of cotton-wool, and by experience in the mode of employing

* The converse is also noticed occasionally, for a patient suffering from ulcerated sore throat has complained to me of a pain in the ear coming on whenever she spoke. There the irritation was evidently applied to the pharyngeal branches of the vagus and transferred to the auricular branch.—Ed. *Pract.*

it, been able to stave off during nearly seven years any heavy cold in the head. Sore throats in the same case are always much benefited by it, and bad colds on the chest, though not cured by it, are invariably much mitigated. It may be used as a valuable preventive when travelling in cold weather, or when exposed to draughts.

MOBÈCHE ON THE EYE IN GENERAL PARALYSIS. Dr. Mobèche (*Annales Medico-Psychologiques*, November, 1874), contributes an article on the condition of the eyes in general paralysis of the insane. The early writers, he says, in their accounts of this disorder, made no mention of the state of the eyes. M. Bailarger was the first who paid particular attention to it. Other observers are MM. Lasèque, Moreau de Tours, Marcè, Dagonet, Billod, and Ach. Foville. The chief point to be noted is the inequality of the pupils, which is sometimes very marked, sometimes very slight. It may depend on the dilatation of one pupil or on the contraction, though this is far less frequent. The contractility of the iris is often affected, and it does not readily contract or dilate. This does not depend on any adhesions, for it dilates readily under atropine. Not only is there inequality of the pupils, but in a considerable number of patients the opening of the iris has lost its circular shape, and assumed a variety of conformations. When it is contracted its contour is almost always irregular, angular, or elongated. Even the pupils which are normal in size are often altered in shape. Sometimes they are elliptical, sometimes they become quadrilateral or triangular, instead of circular, or they may be circular in half or two-thirds of the circumference, and polygonal in the rest. At the commencement of the malady the changes take place frequently; but the writer has never seen a dilated pupil return to its normal size while its fellow was in turn dilated. The alterations were always observed in the same pupil. He is of opinion that defective vision is common in general paralytics, but is not discovered unless accurate methods of testing it are employed. This weakening of sight is due to the dilatation, and not to any affection of the retina, for if it is overcome artificially the sight is as good as that of the other eye. As to the causes of this inequality authors differ. M. Billod thinks it due to a lesion of the oculo-motor nerve, on which the contraction of the iris depends. M. Voisin finds it in the great sympathetic, and its effect on the radiating fibres of the iris; when the sympathetic is excited the pupil dilates; when it is paralysed, it contracts. Dr. Mobèche thinks it may be due sometimes to the one cause, sometimes to the other, or that the retina may become insensible and dilatation take place without lesion either of the oculo-motor or of the sympathetic. Such defects as amblyopia and amaurosis are not, he thinks, common in general paralysis, but may be found if carefully looked for, and are often overlooked because they are confined to one eye; neither is the amaurosis complete, but a certain degree of sight remains. Both the latter, and also paralysis of the third nerve, have been found before general paralysis had appeared.

G. FIELDING BLANDFORD.

MATHEWS ON ANEURISM OF THE ABDOMINAL AORTA SUCCESSFULLY TREATED BY IODIDE OF POTASSIUM.—Dr. T. M. Mathews, of Mount Enterprise, Texas, reports in the *American Journal of the Medical Sciences*, January, 1875, that during the past

winter he was called to attend Mrs. W., aged thirty-eight years. She had been married twelve or fifteen years, but had never had any children. He failed at the time to detect any cause for her general ill health; but in April last he discovered a large aneurism of the abdominal aorta, extending from under the sternum obliquely downward to below the umbilicus. Having seen quoted on page 539 of the *American Journal of the Medical Sciences* for April, 1874, an article by Dr. George W. Balfour on large doses of the iodide of potassium in such cases, he determined to give the drug a trial. He at once put the lady upon twelve and a half grains dissolved in the syrup of sarsaparilla three times a day, and increased the dose each day till it reached fifteen grains. He then gave fifteen grains four times in the twenty-four hours. The patient began at once to improve; the large doses seemed at first to irritate the stomach a little, but this soon passed away. When he began the use of the remedy, the lady was confined closely to her bed; she could not sleep unless under the influence of chloral. After five months, she was able to be up nearly all the while; slept without the soporific; rode about, even on horseback, a good deal, and was apparently in very good health. The aneurismal thrill and the bruit, once very distinct, were nearly absent, though the remains of the 'sac' could be distinctly felt, yet very much smaller than it was at first. He used nothing but the iodide of potassium, except during June, when he gave alternately with the iodide doses of a drachm of fluid extract of ergot, and five minims of tincture of digitalis. He had kept up the use of the iodide steadily, except for two weeks. At the time of reporting, he was giving iodide of potassium, gr. v, and carbonate of ammonia, gr. iii, three times a day.

HALL ON EMETICS IN THE COLD STAGE OF AGUE.—Surgeon A. R. Hall, of the Army Medical Department, writes (*Practitioner*, February, 1875): 'A very successful mode of treating the cold stage of ague, and one extensively employed by medical men in India, is to give an emetic at the commencement of the stage when shivering first begins. The emetic I myself employ is sulphate of zinc, as it does not leave so much depression afterwards as ipecacuanha, and half a drachm of sulphate of zinc is usually found sufficient, followed by copious draughts of hot water, say three or four pints, if the patient can be induced to swallow them. This generally induces free vomiting, and the shivering fit is as a rule cut short at once, and the hot stage, with its subsequent perspiration, quickly follows. The mode of action I conceive to be that the emetic induces a state of relaxation of the muscular fibres of the vessels, and thus promotes free circulation through the surface extremities, lungs, and system generally. I believe that in the cold stage of ague we have a condition similar to the collapse of cholera, though in a much milder form. It has been frequently noticed by medical men in India that the cold stage of remittent fevers can hardly be distinguished from the collapse of cholera, and I have myself felt the breath of a person suffering from remittent fever nearly as cold as in a case of a cholera patient.'

SURGERY.

GÜNTNER ON THE GRAVITY OF COMPOUND FRACTURES OF THE FEMUR.—Professor Güntner, of Salzburg (Betz's *Memorabilien*, Heft 10, 1874), discusses the probable causes of the dangerous character of compound fracture of the femur, especially of fracture due to gun-shot injuries. Attention is directed in the first place to the conditions and results of a clean and intentional wound of the thigh as in amputation, and to the very great fatality of this operation as compared with that of removal of any other limb. This difference is believed to be due to the quantity of muscular tissue which surrounds the femur, the arrangement and size of the femoral muscles, and the influence exerted by them on the stump. On the surface of a transverse section of a healthy thigh is presented a complex system of membranous tubes and sacs surrounding and enveloping the bellies of muscles, vessels, and nerves. Each of these sacs may become the starting-point of inflammation, set up by the frequent contraction of the muscles arising from the pelvic bones and from the femur. A frequent result of this muscular contraction is the so-called conicity of the stump, which, through causing exposure of the extremity of the bone and the medulla, constitutes an element of danger. If speedy and healthy occlusion of these sacs and of the medullary canal be prevented through secondary hæmorrhage, or if the exudation do not possess the proper degree of plasticity, on account of the unhealthy condition of the patient, there is great risk of purulent infiltration and infection. Although in the fore-arm, as in the thigh, there is an extensive muscular apparatus, and a complex set of membranous sacs and of sheaths, still amputation in the former limb is usually successful. This Dr. Güntner attributes to the facts that the muscles of the fore-arm arise from the arm or upper portion of the fore-arm, are not so powerful as those of the thigh, and soon terminate in long tendinous cords. In the relatively thin forearm the results of inflammatory action are soon revealed, and exit may at once be given to pus. In a thigh-stump, on the contrary, widely spread inflammatory action and extensive purulent deposition may take place without the manifestation of any external sign, until it is too late to interfere with any prospect of success. The danger of these secondary processes is in-

creased by the existence in the thigh of a large network of lymph-vessels, always ready to take up deleterious matter and to carry it into the system. In addition to the above-mentioned sources of danger, there are others not less important; the extremity of the bone through muscular action and retraction of the soft parts may, together with its medulla, be exposed to external influence, and so become affected with more or less extensive necrosis attended by profuse suppuration, or with osteomyelitis and osteophlebitis, which frequently give rise to pyæmia. In discussing the means by which some of these conditions of danger might be prevented, Dr. Güntner states that amputation by flaps should be preferred to the circular method, as by the former the speedy occlusion of the sheaths and membranous sacs about the muscles is better favoured, and the bone and vessels are more effectually protected from external influences. In case of obstinate hæmorrhage from a large vein, the application of a fine ligature is to be preferred to pressure by a plug of charpie or any other foreign body. All bleeding, he insists, should be arrested before the flaps are brought together. Muscular contraction may be prevented by firm bandaging of the stump from the pelvis downwards, or, if this fail, by the administration of opiates. Great as are the risks which attend a carefully performed amputation of the thigh, it may be readily conceived that still greater danger is associated with an accidental compound fracture in this region, if we bear in mind the main probable results of such an injury. The soft parts are much contused, and often crushed; the skin and subjacent structures are divided by one or more wounds, which are always irregular and may be of considerable extent; nerves and vessels are lacerated, and there is more or less extravasation of blood. The general grave complications of such a lesion are loss of blood and concussion of the nervous system, indicated by stupor or commotion. As a cause of early death after compound fracture of the femur, Dr. Güntner mentions a form of septicæmia to which he thinks too little attention has been hitherto devoted, viz., septicæmia through diffusion of gases. This is to be met with in cases only where there has been rapid decomposition of organic tissues after much crushing of soft parts or from extensive infiltration of gangrenous excretions. This presents the typical form of septicæmia, since all other forms are more or less complicated by pyæmia. Dr. Güntner is inclined to regard it as a probable but not frequent cause of speedy death in puerperal affections, endometritis, and metrophlebitis.

FUCHS ON A CASE OF LIGATURED PENIS.—This case is reported in the *Medicinisch-Chirurgisches Centralblatt*, no. iii. 1875. In November of last year Herr Julius Fuchs was called one afternoon to a healthy and robust boy aged six years and a half, who for some time previously had been in the habit of passing his urine in bed, for which he was often rebuked, but never actually punished. The following conditions were presented: extreme phimosis, the penis swollen to about three times its natural size, the prepuce much swollen and marked on each side by patches of sloughing caused by the friction of the penis against the inner surfaces of the thighs during walking. About one inch in front of the root of the penis was an annular granulating wound around the whole organ, involving the skin, subjacent cellular tissue, and much of the thickness of

the corpora cavernosa, extending almost as far as the urethra. The edges of this wound were between six and eight lines apart. The surface of the scrotum was red and eczematous, and the inner surfaces of the thighs studded with pustules. The urine was passed in drops, and with much pain. No accurate information as to the cause of this condition could be obtained from the boy, who, when questioned, made contradictory and improbable statements.

On the following morning, Herr Fuchs, on carefully examining the wound, observed among the granulations a dark line, which proved to be a portion of a thread which the patient had bound tightly round the penis, evidently with the purpose of preventing a nocturnal and involuntary flow of urine. This thread was at once divided and removed. With perfect rest, and the use of camphor lotion and cold applications, the case progressed favourably. The preputial sloughs were thrown off on the third day; the eruptions on the scrotum and the inner surfaces of the thighs soon disappeared, and the urine passed freely without causing pain. At the end of the year the penis, with the exception of the prepuce, which remained hard and swollen, had regained a healthy condition.

W. JOHNSON SMITH.

BUROW ON THE PREVENTION OF THE PASSAGE OF BLOOD INTO THE LARYNX, IN OPERATIONS ON THE JAWS, ETC.—Dr. Burow of Königsberg (*Berliner Klinische Wochenschrift*, Feb. 1875) publishes two cases of operations on the jaw, in which he employed Rose's method of placing the head so as to prevent the blood passing into the trachea or pharynx. There are two grave objections to Trendelenberg's method of producing anæsthesia in such cases, which have been frequently observed, viz., the uncertainty and insufficient strength of the tube of the apparatus, and the difficulty of fixing it for the tracheotomy, which is the preparatory step; again the elastic collar often bursts at the moment of expiration, so that it is necessary to delay the proceedings; moreover the best caoutchouc will lose its elasticity; circumstances which would place the country practitioner in difficulties. Tracheotomy is itself an important operation, and is, of course, liable to its own mishaps, which renders its being an adjunct to others still more undesirable.

Rose proceeds as follows. The patient is to be placed with his head in such a position that all danger which may occur from blood being in the mouth during deep anæsthesia may be prevented. He should be anæsthetised lying on his back if possible; then the cushion under the back being removed, so much of his body should be drawn over the edge of the operating table that his head should hang down, with the crown vertical, in which position it should be fixed by a trustworthy assistant kneeling at the side. The operator sits (or stands) in front of the patient, consequently he has to invert all his incisions (*i.e.*, make them from chin to vertex) and the blood thus flows out partly through the mouth, but the greater part of it by the choanæ and nose.

The operations for which Rose has generally employed or has proposed this proceeding, are resection of the upper jaw, uranoplastics, rhinoplastics, laryngotomy, tonsillotomy in children, and hare-lip cases, the latter without an anæsthetic, so as to prevent the swallowing of blood and the resulting disturbance of the digestion, which often cause

death. Tonsillotomy is, as a rule, performed without an anæsthetic in children, but it is sometimes necessary, or even desirable. Hueter, in one case, performed tracheotomy, and inserted Trendelenberg's tampon-cannula.

[In a case observed by the reporter some years ago, the method here described would have been invaluable; a patient was being operated upon for strabismus, and under anæsthesia, when suddenly he became livid and presented all the symptoms of threatened suffocation, it was discovered that the blood had found its way into the back of the pharynx, though a small aperture immediately below the lower eyelid, resulting from syphilitic necrosis of the superior maxilla, and which had also destroyed the floor of the antrum.—*Rep.*]

EDWARD BELLAMY.

MARSHALL ON A NEW OPERATION FOR VARICOSE VEINS.—Mr. John Marshall recently gave a lecture at University College Hospital (*Lancet and British Medical Journal*, January 23) on the treatment of varicose veins; in the course of which he remarked that the treatment by subcutaneous ligature, now generally employed, was not altogether free from risk, and that its results were not always satisfactory. He then proceeded to describe an operation which, he believes, will prove a more speedy, effectual, and safer cure than that now in use. It consists in excising a considerable length of the vein where it is most enlarged, and is performed as follows. The course of the vein having been marked with ink, a pin is passed under it at each end of the part to be removed; the limb is now emptied of blood by Esmarch's bandage; the skin is divided along the marked line, and the vein, previously secured by figure-of-8 ligatures passed over the pins, cut across at each end and dissected out; the wound is then dressed after Lister's method. Mr. Marshall afterwards showed what had been a very bad case; ten inches of vein had been removed, and a rapid and complete cure effected.

FIRMAN ON PHYTOLACCA DECANDRA IN THE TREATMENT OF MAMMARY INFLAMMATION.—Dr. Firman, of Ohio, calls attention, in the *Philadelphia Medical and Surgical Reporter* of January 9, to the special virtues of *phytolacca decandra*, or poke plant, in cases of inflammation of the mammary gland. The plant is common in southern Europe, and also grows wild in the United States, where it has long been known as a popular remedy for 'garget'—an inflammation in the udders of cows. Dr. Firman says it is equally effectual in the human subject. He gives internally a fluid extract made from the root, and applies a more concentrated solid extract locally; under this treatment, cases of threatened abscess of the breast rapidly resolve. Several equally favourable reports on the antiphlogistic or sedative properties of this plant have appeared in the American medical papers during the last year or two, *e.g.* one by Dr. Biggers, in the *American Journal of the Medical Sciences* for January, 1873. MATERIA MEDICA AND THERAPEUTICS.

TREATMENT OF COLD.—The editor of the *Archives of Electrology and Neurology*, in the number for March, 1874, says: We have long been in the habit of using what we call a 'cold-powder,' which we have found of great value in breaking up colds when taken in time, and in modifying their force when taken late. The prescription is as follows. Dissolve five parts of camphor in ether to the consistence of cream: then add carbonate of ammonia, four parts; opium-powder, one part. Mix and keep in a tightly corked bottle. The dose is regulated by the opium, and ranges between three and ten or fifteen grains. We have been accustomed to prescribe it for our friends by the finger-nail full, or as much as one can put on the finger-nail. This powder may be taken in a little water just before retiring, by preference, or at any hour of the day, whenever there is a suspicion of having caught cold. If need be, a moderate dose may be taken several days in succession.

The advantages of this powder are very great. 1. The taste is agreeable, or at least it is not disagreeable. Even the bitterness of the opium is mostly neutralised by the camphor and ammonia. No child objects to this powder. 2. It is singularly and inexplicably efficacious. We believe it to be more efficient than Dover's powder, and incomparably more agreeable. In some cases it produces a gentle perspiration; in others, this especial effect is not observed. It is so easy to take, and so harmless in small doses, that it is well and safe to take it whenever we become badly chilled. We first called attention to this cold powder in 1869. From various sources, lay and medical, we hear that it accomplishes all that is here asserted, and we therefore earnestly recommend it to the profession.

DE MUSSY ON INJECTIONS OF IPECACUANHA.—Dr. De Mussy writes to the *Practitioner* that in chronic dysentery, and even in common chronic diarrhoea, injections of decoction of ipecacuanha into the intestines are a common practice in Peru and in some

other countries of South America. He has used this remedy with success in some cases of diarrhoea unchecked by other means. His formula is this: boil one drachm of ipecacuanha-root for ten minutes in five ounces of water; let it infuse for one or two hours, strain off, and make use of the decoction as an enema. Habitually, this enema is wonderfully well tolerated. No painful sensation nor irritation of the bowel attend these injections in the greater number of cases. They can be retained for several hours without any difficulty, and even occasionally with a feeling of comfort and relief.

DOWSE ON THE TREATMENT OF ACUTE RHEUMATISM.—During the last three years Dr. Dowse (*British Medical Journal*, January 9 and 23) has treated cases of acute rheumatism very successfully by packing the patient in blankets wrung out in hot water. This causes first, elevation of temperature, and then copious sweating, which is soon followed by diminished pyrexia and great alleviation, or even cessation, of pain in the joints. Three applications are usually sufficient. He gives full directions and some important cautions.

OBSTETRICS AND GYNÆCOLOGY.

BARKER ON THE AGE OF WOMEN WHEN THE CAPACITY FOR CHILDBEARING CEASES.—Dr. Fordyce Barker read a paper on this subject before the New York Medical Library and Journal Association, on November 20, 1874. The object of this paper was to show that, physiologically and as a matter of experience, there are limits in the reproductive functions of women. The ordinarily accepted notion that menstruation and conception are inti-

mately connected is not borne out by facts, as many women who menstruate regularly without any apparent pathological cause are sterile; besides, many women have conceived and borne children in whom the catamenia have entirely ceased for some years, and who, in fact, have never menstruated at all. There are cases on record where females have had irregular and scanty periods previous to marriage, which entirely ceased when they married, and yet have had children. Dr. Barker met with an instance of the kind where the person had ten children, and also with cases in which children were born two, three, and five years after the cessation of menstruation. He therefore concludes that ovulation and menstruation, although often coincident, do not stand to each other as cause and effect. Ovulation does not always occur at the time of menstruation; the latter may therefore be viewed as an accident and incidental phenomenon, a mere flux of blood from the interior of the uterus at stated periods, irrespective of ovulation. Ovulation is essential to impregnation, menstruation is not. The presence of the catamenia in a female over fifty-five or fifty-eight years is no proof of ovulation. With senile atrophy of the ovaries, ovulation and conception cease. This period is reached, as a rule, between the fortieth and fiftieth year; but, in very exceptional case, this change does not occur until one, two, three, or four years later. This has been proved by *post mortem* examinations; and, in addition, there is but one properly authenticated case of childbearing at the age of fifty-five years, reported by Dr. Davies, of Hertford, England. There are, however, many known and reliable instances of women giving birth to children between the ages of fifty and fifty-four; Dr. Barker personally attended three women who were above fifty, one being fifty-three years of age. Several cases which have been accepted by writers of medical jurisprudence, where delivery had taken place beyond the age of fifty-five, were discarded as not supported by such evidence as would be regarded as conclusive in a court of law; for, where statements were made opposed to the universal experience of mankind, and the probabilities stood as a million to one, scientific men could accept no lower standard. His final conclusion was, that, from the experience of mankind, the laws of physiology, and the decisions of the courts of law, no medical witness was justified in declaring a woman capable of childbearing after the age of fifty-five years old.

In the discussion that took place afterwards, Dr. Pallen stated that he would be loth to say that a woman who menstruated regularly, and in whom there were no indications of the retrograde metamorphosis of age, was incapacitated from childbearing although beyond the age of fifty-five. There were also cases in which women menstruated regularly and bore children, and yet had extensive disease or degeneration of the ovaries.

Dr. Munde believed that menstruation and ovulation went together, and when one ceased, the other did also. He related many cases to prove this; at the same time allowed the exceptions which went to prove the rule, that conception ceased with menstruation.

Dr. Caro stated that, in Sicily, the government recognised the possibility of childbearing from the age of eleven years and two months to the age of fifty-four or fifty-five years. He knew of one case, where a woman had thirty-one children; the last was born when fifty-four years old. A double uterus was sus-

pected, as she gave birth to a child every six months. Unfortunately no necropsy was made on the death of the mother.

In answer to the question, what evidence Dr. Barker had that menstruation and ovulation did not necessarily occur together, he replied: (1) Because the one might exist without the other, as proved by authenticated cases; (2) Cicatrices were found in ovaries, indicating rupture of the Graafian vesicles many years previous to menstruation, and also fresh cicatrices had been found in old women who had ceased menstruating for a long time; (3) There were eight well certified cases in which menstruation continued after the extirpation of both ovaries; therefore ovulation was impossible. To him these facts were conclusive evidence of the independence of the two functions.

MARTIN AND OTHERS ON ENUCLEATION OF FIBROIDS.—At the Congress of German Naturalists and Medical Men, held in 1874 at Breslau, in the gynaecological section (*Berliner Klinische Wochenschrift*, Nov. 23, 1874), Dr. A. Martin read a paper on enucleation of intraparietal fibroids. He had enucleated five intraparietal myomata of the body of the uterus in the Gynaecological Klinik at Berlin. He entered very fully into the minute details of his own personal experience. Having described the anatomical relations of these five apparently particularly interesting tumours, he endeavoured to determine the precise period when the operation should be performed. He found it laid down that the tumours should be allowed to grow until they became submucous, and until the lower segment of the uterus was prepared by increasing contractile activity for their expulsion. Dr. Martin agreed in this view. It was under these conditions that he operated, by which means, he always considered, difficulties were diminished and the dangers lessened. All the usual enucleating instruments were discarded, and the shelling out the tumours performed with only a few incisions. To overcome some of the difficulties he invented a kind of forceps, with the upper portion of the blades armed with guarded and applicable hooks. Authorities he found varied much as to whether the operation should be completed in one sitting or in two. The relator thought the operation *à deux temps* only justifiable when the tumour was very rich in fibres and poor in blood-vessels. His after-treatment was directed purely to symptoms. Of the five patients four recovered in a short space of time; one died on the third day after an operation *à deux temps*. Out of the fifty-one recently published cases there was only a mortality of 14 per cent., whereas out of those collected by Dr. West, and performed a few years ago, the mortality stood at 50 per cent.

In the discussion that ensued, the proposal to operate on intraparietal fibroids met with much opposition. Dr. Fränkel, of Breslau, cautioned against operating for veritable intraparietal fibroids, as a method fraught with too much danger. Enucleation was only applicable in the submucous variety, to which he believed Dr. Martin's cases were referable.

Dr. Neugebauer, of Warsaw, and Dr. Spiegelberg, coincided in this opinion. The latter maintained that it was only those fibroids that were met with during labour, and in which the internal os was dilated, that were amenable to intrauterine operation; whereas true intramucosal fibroids, *i.e.*, those surrounded on all sides by a nearly equal layer of

uterine tissue, could not be extirpated *per vaginam*, or only when they were of small size, and situated low down.

PAULI ON DRAINAGE IN OVARIOTOMY.—At the last meeting of the Association of German Naturalists and Physicians, Dr. Pauli, of Posen (*ibid.*), spoke on ovariectomy with drainage; and from the result of two witnessed cases he recommended Sims's suggestion of prophylactic drainage with large adhesions, keeping the abdominal cavity open for some time, continuous cleansing with sponges, and also with depression of the pedicle. Drs. Martin, Ebell, and Spiegelberg agreed with Dr. Pauli, and as the result of their experiences strongly advocated this method. The latter (Dr. Spiegelberg) in his last case of ovariectomy, in which the pedicle became repeatedly untied and sank down, he gave up the trial with the drainage. The patient, it is true, recovered, but from the bursting of an abscess into the peritoneal cavity got diffuse peritonitis and made a difficult recovery. In a case where the cyst ruptured into the peritoneum during the operation, with Sims's drainage, the patient became rapidly well, with hardly any reaction.

W. C. GRIGG, M.D.

BROWN ON THE USE OF ERGOT AND BORAX.—Dr. C. Brown (*Transactions of the Medical Society of the State of Pennsylvania*) says: In those cases where the os uteri is dilated or dilatable, and the uterine pains are tardy, I generally give a full dose of powdered ergot, combined in equal proportions with borax. I find that this preparation of borax and ergot is better borne, and is more durable in its action than ergot alone. It not only stimulates the uterus to action, but it continues its effects longer. Generally, I have found that after giving one or more doses of this preparation before delivery, my patients are less liable to severe hæmorrhage. In uterine hæmorrhage, I have found nothing to excel ergot as a styptic. It seems to have a specific effect in this class of hæmorrhages.

TOXICOLOGY.

PAYNE ON POISONING FROM CORROSIVE SUB-LIMATE GENERATED IN THE MOUTH, FROM AMALGAM PLUGS IN THE TEETH.—According to Dr. J. Payne (*Chicago Med. Journal*, August, 1874), 'Neither Asiatic cholera, nor small-pox, nor any malarious disease, is doing half the mischief in the world that is being done by this poisoning. Every medical man has undoubtedly had numerous cases of it, but never knew what it was.' From Dr. Payne's observations the patient is liable to be treated for 'dyspepsia, neuralgia, paralysis, consumption, and numerous throat-diseases.' No medicine gives any relief, and yet the patient does not die; 'he will again rally and again be prostrated.' There is such a 'resemblance in the symptoms to nearly all the diseases to which flesh is heir, that the physician is led to treat for some disease which seems to be a very clear case, but his patient gets worse.' In more than twenty cases that Dr. Payne had, nearly all had been pronounced by some physician as having consumption.

Dr. Payne 'has not time to detail the manner in which the corrosive sublimate is formed in the mouth,' further than to say that the mercury driven off from the plugs by the heat of the mouth combines with the chlorine in the fluids of the mouth or saline substances in food, then passes into the stomach, and produces slow poisoning.

Dr. Payne evidently feels strongly the importance of his case, and declares that 'there are some twelve thousand dentists in the United States doing a wholesale business in this poisoning,' and he asks the co-operation of the State Medical Society to assist in getting an Act of Congress passed, making it a 'penitentiary offence to place any poisonous substance in teeth that will injure people.'

[Patients may choose their symptoms from anything ranging between paralysis and consumption; they may either slowly become 'a total wreck,' or they may suddenly appear about to die, then rally, and yet again become prostrated.]

From the reporter's knowledge of the action of properly applied amalgam-plugs in the teeth, he is led to the conclusion that the experience of Dr. Payne is unique. The article will, however, doubtless, receive the attention that it deserves.—*Rep.*

OAKLEY COLES.

WARREN ON POISONING BY CARBOLIC ACID.—Mr. F. Warren, Resident Surgeon at Stevens' Hospital, Dublin, relates (*Irish Hospital Gazette*, January 1) the case of a man who drank some solu-

tion of carbolic acid intended for disinfecting purposes, mistaking it for whiskey. Its action was most rapid; he immediately became insensible, falling down suddenly as if in a fit; on his recovery he said that he remembered nothing whatever after tasting the liquid. When brought to the hospital he was suffering also from extreme syncope. The stomach-pump was used, stimulant enemata administered, and after about seven hours he recovered his consciousness and gradually rallied from the depression. An attack of acute gastritis followed. The urine passed the day after the accident was almost black, but was free from turbidity, and no trace of carbolic acid, blood, or albumen could be detected in it.

J. W. LANGMORE, M.D.

MEDICAL CHEMISTRY.

FOWLER ON A MODIFICATION OF TROMMER'S TEST FOR SUGAR.—Dr. George B. Fowler made some interesting remarks before the North-Western Medical and Surgical Society of New York (*New York Med. Journ.*, June, 1874), relating to the various tests of urine, and particularly with reference to a modification of Trommer's test for sugar. In order to use this test, take one ounce of water and add to it one drop of honey; apply Trommer's test to a portion in a test-tube, and the chemical reaction will take place. Take one ounce of urine and add to it one drop or as much honey as you please; apply Trommer's test, and a transparent molasses-colour will result. Take the precipitated red oxide of copper which resulted in the watery solution in the first case and add boiling urine; the red precipitate will immediately disappear. The urine, therefore, possesses the property of dissolving the red oxide of copper, upon the appearance of which Trommer's test depends. But a certain quantity of urine can only dissolve a certain amount of the copper. So, if we add an excess of copper, this excess will be precipitated by the sugar, and the usual reaction will show itself. But when three or four drachms of urine are used, as is always the case, the quantity of potash-solution which will have to be added in order to produce a clear blue colour, will overrun an ordinary-sized test-tube. Therefore, take from five to ten drops of the suspected urine and two or three drops of the solution of sulphate of copper a drachm to an ounce. Then pour in the alkali until a transparent blue colour appears. Now boil, and the reaction will be perfectly distinct and satisfactory.

DERMATOLOGY.

TILBURY FOX ON ITCH.—In a lecture reported in the *British Medical Journal* for January 23, Dr. Tilbury Fox remarks on the different aspect which scabies presents in hospital and in private practice. Well-to-do patients apply earlier for advice, when the acari are as yet few in number and confined to limited areas; the furrows also are not rendered visible by dirt; it is necessary to look at the skin obliquely in order to detect them. The secondary eruptions, which are a prominent feature in hospital cases, are often scarcely present in private patients. The consequence is that the disease, when first seen, is frequently not detected. Dr. Fox suspects scabies if a patient come complaining of

nocturnal pruritus affecting the lower part of the abdomen, the inner part of the thighs, and the forearm or hands. He states also that such cases, when they are diagnosed, are often treated too energetically, so that more irritation is caused by the remedies than by the original disease. He orders a dilute sulphur ointment (half-a-drachm of sulphur to an ounce of lard) to be rubbed into the parts most affected, e.g., the hands and penis, for three nights and mornings, and just smeared over adjoining parts. He then orders a soap-bath and change of linen, and after that waits to see if the irritation does not subside, or only orders some astringent or emollient application.

DUCKWORTH ON WAXED PAPER AS A SUBSTITUTE FOR LINT AND OILED SILK.—Dr. Dyce Duckworth, of St. Bartholomew's Hospital (*Archives of Dermatology*, January), when using ointments for the cure of disease or abrasions of the skin, applies them on waxed paper instead of lint. This is the material used by pharmacists for covering gallipots, etc.; it consists simply of thin tissue-paper dipped in melted wax. A piece of this is cut of a size sufficient to extend beyond the margins of the sore place; the ointment suitable to the case is then smeared on the centre, not too thickly, and it is then carefully adapted to the affected part. It is adhesive, so that there is no necessity for strapping or bandaging; it is very cheap, and it is cooler than lint. Dr. Duckworth uses it even for extensive eczema of the limbs.

J. W. LANGMORE, M.D.

LAGRANGE ON SCLERODERMIA.—Dr. Lagrange, in his *Contribution à l'Étude de la Sclérodémie avec Arthropathie et Atrophie Osseuse* (Paris, 1874) gives an account of a necropsy, which he performed on a patient who presented all the characteristics of scleroderma, and of another case which came under his notice. The facts observed by him induce him to come to the conclusion that scleroderma is originally set up by a chronic inflammation of the skin and the subcutaneous cellular tissue, which may go deeper, reach the bones and the articulations, and may bring on, as a secondary result, by anatomical lesion of the peripheric nervous filaments, some comparatively unimportant trophic disturbances, which are only of the second order. Nothing gives reason to rank scleroderma as a primary trophic disturbance; the spinal marrow, nerves, and muscles, not having shown any considerable alteration on *post mortem* examination.

REVIEWS.

- Histoire de la Peste Bubonique en Perse.* Premier Mémoire. Pp. 42.
Histoire de la Peste Bubonique en Mésopotamie. Second Mémoire. Pp. 91. Par J. D. THOLOZAN. Paris, 1874.

The following are the conclusions arrived at by Dr. Tholozan in these two instructive memoirs.

Persia has never been, in any portion of it, a country in which plague has prevailed as an endemic. No universal epidemic of the disease has ever been observed in that country; the half at least of it has always escaped the plague.

The epidemics appear almost always to commence in the cold and mountainous part of the north-west, where the little outbreak of 1871 appeared. They have been separated from each other by intervals, varying from ten to sixty years.

Science has not recorded a single instance of plague of purely Persian origin, introducing itself from Persia into Turkey; the plague of 1829-31 passed from Turkish Armenia into Persia, and thence it penetrated into Mesopotamia.

The small epidemic of 1871 is an interesting etiological study; it forms a pendant to the epidemic of Hindî in 1867, and shows that the points of origin of a bubonic fever may be found as readily in mountainous districts at a high elevation, as in the low and humid plains of Mesopotamia. This had already been proved in the bubonic fever of the slopes of the Himalaya.

The great epidemics of plague in Mesopotamia in the eighteenth and nineteenth centuries have only been three in number. Their origin appears to have been exotic in this sense, that the disease first developed itself in neighbouring districts. Their course was invariably from the north or north-west to the south—from the sources of the large rivers towards their mouths. The epidemics of 1773 and of 1831 were the most severe, and spread as far as the coasts of the Persian Gulf. The epidemic of 1800 was less general, and ceased before reaching the sea.

The commencement of these three epidemics was in the winter season, their development was in spring, and their decline and extinction were in summer. Their annual recurrences followed the same rule. After an autumn incubation of at least three months, the germs of the malady reappeared in some localities in winter and in spring. These new explosions repeated themselves sometimes for three years. The disease seems to have had successive degenerations, and to have lost a part of its contagiousness, or of its power of being transported to a great distance.

With the exception of some epidemic years, and some consecutive manifestations of short duration, no endemic plague has been observed in Mesopotamia, like that which has prevailed in modern times in Egypt, in Armenia, in Georgia, and at Constantinople.

The small epidemic of plague in Mesopotamia in 1867 was of local origin. It was preceded by grave pathological phenomena, which remind us of the *pestilential medical constitutions* which sometimes preceded the arrival of great plagues in certain countries of Europe.

This localised epidemic obeyed, in its commencement, its progress, and its extension, the same laws as the three great plagues which preceded it. It showed itself, as they did, after a period of complete absence of about thirty years.

The facts most closely connected with the etiology of plague in Mesopotamia are—its following after a certain number of years of immunity, and, in the case of great epidemics, the presence of the disease in the mountainous districts of the north.

The summer season has always moderated, lessened, and arrested the development of the plague, in

the country of which Dr. Tholozan speaks. The exceptional heat of that district, especially along the shores of the gulf of Persia during the months of June, July, August, and September, appears to have acted as efficaciously in extinguishing the disease, as in the celebrated experiments determining the temperature necessary to destroy the microphytes of wine, or bacteria in disease.

As a corollary to these statements, it may be added, that several other zymotic diseases are extinguished in Mesopotamia during the hot season. Cholera is a remarkable example of this. From the comparison of a number of epidemics of it, it is ascertained that it follows the same rule as the plague; that it ceases entirely during the great heats, to reappear in autumn, winter, and spring.

These views, which show the influence of seasons and the great physical forces on epidemics, are without doubt more rational than the exclusive system of contagion. That system, which only looks out for frontiers to defend, and for barriers to erect, pays no more regard now than in former centuries, to the natural march of those great phenomena which we term epidemics. It only occupies itself with the question of the transport of morbid germs, and does not understand that the conditions of this transport are enveloped in the greatest mystery. Nature itself often opposes more effective obstacles than we can to their transmission, and sometimes it finds means which are quite unknown to us for resuscitating and disseminating those germs.

M. Tholozan, after pointing out that the inhabitants of the lower portion of Mesopotamia, like those of the delta of the Nile, are strong and healthy, offers a few words of comparison on those districts. These two districts have been considered for centuries the seat of permanent endemic plague; but history shows that the plague has not always existed in Egypt. The efforts made to explain the origin of the plague after the Mussulman conquest, from the neglect of hygienic conditions, have not been successful. The plague has existed in Egypt for many years; it has then disappeared, only to come back after a time, while there is nothing to explain satisfactorily the cause of its coming or of its going. It has been shown that in Mesopotamia, which is better adapted in appearance to nourish the disease, it has only made rare appearances for two centuries. These matters require to be studied afresh in their bearings.

J. MACPHERSON, M.D.

Diseases of Tropical Climates and their Treatment.

By J. A. B. HINTON, M.D., F.R.G.S., Surgeon-Major, African Medical Service.

We opened this book with a sincere desire to find in it something to commend, but after a candid examination we fear that, as honest critics, all we can conscientiously praise are the good intentions and diligence of the author.

Dr. Hinton is, we understand, a native of the West Coast of Africa, who was educated in this country for service in his native land; he therefore, comes before us with a strong claim to generous treatment. Still, we must be just as well as generous, and must therefore say we think our author was ill advised when he rushed into print. We have no doubt that Dr. Hinton can treat the formidable diseases of his native land with creditable skill, although he cannot write about them in a way calculated to aid others in their study. The work is made up chiefly from the writings of well-known

authors on tropical medicine, with frequent reference to the lectures by Professor Maclean at Netley; but the author cannot be said to have digested, much less assimilated, his materials, and he has not literary skill enough to present either his own observations or those of others in a useful or intelligible form to his readers. The descriptions of disease are confused; the pathology is often out of date; and the composition beneath criticism. We are really concerned to have to write of the well-meant efforts of a very meritorious man in such terms; but it is a duty we owe to the public and the profession to discourage the publication of books of this stamp. The only purpose they can serve is to injure the reputation of their authors, and to bring discredit on the science and art of physic.

On a Case of Operation for Epithelioma of the Mouth and Tongue. By HENRY MORRIS, M.A., M.B., F.R.C.S. Reprinted from the Reports of the Middlesex Hospital for the Year 1873.

This pamphlet gives a detailed account of a case of cancer of the tongue, which was under observation during almost its whole course, and for the relief of which several operations were undertaken. From May 1871 until June 29, 1873, when he died, the patient was under treatment at the Middlesex Hospital, and the varieties of treatment which were adopted made the case an illustrative one. The disease commenced first in front of the frænum, and, as it spread, it involved both the tongue and the floor of the mouth. On August 13, 1871, the symphysis menti was divided, and the whole of the disease removed. But, as often happens after operations of this kind, the symphysis united very tardily, and it was not till December 29 that the parts could be reported as thoroughly healed. During the early part of 1872 the patient was still an attendant in the out-patient department, and some minor treatment was employed from time to time. In February, 1873, he again applied, having had about nine months immunity from the disease. He had now a deep, irregular, excavated ulcer, occupying the fore part of the floor of the mouth. As this was attended by frequent hæmorrhages, the right lingual artery was tied on June 15, and he left on the 20th. But neither of these operations succeeded in arresting the occasional flow of blood, and the patient died on June 29. It is seldom, we believe, that ligation of the lingual arteries is called for in cancers about the tongue or mouth, and still more seldom that it does any real good. On the whole, this case is an instructive one, and it has been carefully observed and well reported.

CORRESPONDENCE.

CYSTS IN THE BROAD LIGAMENT.

(To the Editor of the MEDICAL RECORD.)

SIR,—In your number for January 13, a case is reported in which M. Auger 'removed a dermoid cyst from between the folds of the broad ligament.' The report states that 'the ovary was not seen,' and that 'the Fallopian tube passed over the upper part of the tumour.' Your reporter remarks that 'the tumour corresponded, in its anatomical relations, with the extra-ovarian cysts, which are affirmed by some to be always unilocular, and derived from the organ of Rosenmüller,' but that, on the contrary, this was 'a cyst evidently of ovarian origin,' etc.

Now, I am not aware that any one has affirmed that tumours between the folds of the broad ligament are necessarily parovarian, in virtue of their position. But it is affirmed that a tumour in this position, whether unilocular or multilocular, with the ovary attached and in a healthy state, perhaps altered in form by mechanical action, is parovarian. The case, as reported, is utterly useless in the settlement of a knotty question, and it is almost idle to speculate on the data here furnished. It may be interpreted thus: That the ovary was not seen probably because it was involved in the mass, and the downward growth of the tumour, in the direction of least resistance, until stopped by the uterus and the pelvic fascia, was simply an accident of the position of the starting-point and the direction of the degenerative process. It is by no means uncommon for an ordinary multilocular ovarian tumour to pass downwards into the folds of the broad ligament and to stretch the Fallopian tube beyond its usual length; and a cursory examination will invariably afford an explanation. Your Reporter adds the remark that 'the case would be more interesting if the ovary, or any remains of it, had been seen.' It would have been much more interesting had the ovary been found healthy.

GEO. GRANVILLE BANTOCK.

[Dr. Bantock appears to have misunderstood the meaning of the first sentence which he quotes—the words are, 'extra-ovarian cysts, which are affirmed by some to be always unilocular, and derived from the organ of Rosenmüller,' not that it has been affirmed that 'tumours between the folds of the broad ligament are necessarily parovarian in virtue of their position.'—*Rep.*]

MISCELLANY.

ACCORDING to the *Gazette de St. Petersburg*, 250 young women are now attending the courses of medicine and obstetrics at the St. Petersburg School of Medicine and Surgery.

THE ARGUMENTUM AD HOMINEM.—The scholastic troubles of the medical academies of Europe seem to have attained a disreputable climax in Spain. The professor of physiology at Barcelona, Signor Varela, was hissed and insulted at lecture by a large number of his pupils, and so far forgot himself as to draw a revolver, and threaten to fire on his tormentors. A terrible disturbance and general scamper were the result. The rector of the university disarmed the professor, but could not appease the wrath he had excited in the minds of his pupils, and the aid of the recognised guardians of the peace was perforce enlisted.

ALCOHOL.—Dr. Richardson, in his first Cantor lecture, gives some information on this much used word. He says that the first employment of the English word alcohol is obscurely recorded. Bartholomew Parr, one of the most learned of scientific classics, taking the usual derivation of the word from the Arabic *Al-ka-hol*, a subtle essence, says it was originally employed to designate an impalpable powder, used by the Eastern women to tinge the hair and the margins of the eyelids. As this powder, viz., an ore of lead, was impalpable, the same name was given to other subtle powders, and then to spirit of wine exalted to its highest purity and perfection. The earliest systematic and truly scientific use of the term that Dr. Richardson could discover is in Nicholas Lemert's *Course of Chemistry* published in 1698. There the word is used as a verb, 'to alcoholise,' and the definition of this is said to be 'to reduce to alcohol, as when a mixture is beaten into an impalpable powder.' The word, says Lemert, is also used to express a very fine spirit; 'thus the spirit of wine well rectified is called the alcohol of wine.'

THE INFLUENCE OF ILLEGITIMACY ON MORTALITY.—At the meeting of the Paris Academy of Sciences on

January 12, M. Gustave Lagneau read a report on this subject, in which he showed that the proportion of illegitimate still-born children in France is approximately twice larger than in legitimate children, viz., sixty-six to seventy-nine in 1,000 instead of from thirty-one to forty-one. This excess of mortality in illegitimate still-born children is due in a certain proportion to criminal practices; but greatly also to the state of privation and poverty in which gestation and delivery take place. In France there are seventy-five illegitimate births in every 1,000 registered, a much larger proportion than in Germany, and the number of these illegitimate births increases in proportion to the obstacles in the way of marriage. During the first year of existence 314 out of 1,000 illegitimate children die, whilst the more fortunate infants born in wedlock only perish in the proportion of 165 per 1,000. This almost double mortality is referable to many causes, which affect the unfortunate little creatures long after their entrance into this world. In fact, out of 1,000 conceptions registered twenty years ago, 640 legitimate children now survive, whilst only 238 illegitimate offspring have lived through the difficulties of their existence, being one-fourth only of the original number.

A NEGLECTED MEMBER.—Many years have now elapsed since Benjamin Franklin published a little book called 'Protest of the Left Hand against the encroachments of the Right Hand,' in which he desired to show how unwise it is to cultivate the physical education of the right hand only and to neglect entirely that of the left. Although his counsels were not attended to at the time, yet the question he raised has continued from time to time to receive the attention of physiologists, some of whom maintain that the extra work thrown on the right hand in which the whole of the right side takes its share, is the cause of the more extensive development of that side of the body in comparison with the left. In support of this opinion the example of the lower animals is adduced, in whom either there is no difference between the two sides, or they present a considerable development of the left side. In the first case, the animals make use of both sides of the body equally; in the second, they use the left as a matter of preference. Physiology offers no explanation of the very ancient custom of making use of the right hand and the right side of the body. Several writers, including Dr. Brown-Séquard and some anonymous contributors to *La Sforza* and the *Revue Médicale de Lyon*, have lately endeavoured to turn public attention to the subject, with the object of cultivating the use of the left hand as much as that of the right. It is asserted that the left hand, if properly trained from youth, could take its share in writing, fencing, painting, and the practice of the fine arts in general; and as a practical outcome of the due use of this almost disused member, it is pointed out that the painful affection known as writer's cramp might be avoided, if both hands were equally available for writing. Dr. Brown-Séquard is of opinion that the powers of the left side of the brain are in abeyance from the disuse of the left side of the body generally. An interesting exposition of his views on the subject will be found in the current number of the *Cornhill Magazine*.

THE NEW AQUARIUM AT NAPLES.—The *Gazette d'Augsbourg* contains some details respecting the new Stazione Zoologica at Naples. The architects of this building have not endeavoured to rival the glories of the aquaria of Vienna and Brighton, but the interest and importance of the aquarium consists in the variety and extent of the collection of marine animals, fish, shells, corals, mollusca, medusæ, crustacea, worms, sponges, starfish, etc., which people the tanks. These tanks contain every animal which inhabits the depths of the sea. The medusæ and their congeners, as well as some other mollusks, do not thrive very well. There are in this aquarium eight large octopods, one of which cut in two a large lobster with which he was having a fight; another one ate up, to the last atom, a live rat, which had been spared by the dogs employed

at the aquarium for hunting those animals. The pumps for supplying the tanks are worked for twelve hours a day; for the remaining twelve hours there is no current of fresh water, and the animals seem to thrive well under these conditions. Last summer some observations were made on the electric ray. An English zoologist, who is preparing a work on the history of sharks, stayed four months at the station, and during that time 400 sharks' eggs were placed at his disposal. This aquarium has thus become a field where naturalists can pursue their investigations, and where they find facilities for pursuing their studies and experiments in the buildings of the establishment itself. The director of the establishment informed the writer of these details that, since it was opened in February last, twenty-two naturalists had already come thither to work in the laboratories. It contains twenty of these rooms, which may be hired, and in fact, are already let to foreign governments or scientific institutions. It is believed that this establishment will exercise a beneficial influence on the development of the biological sciences; it owes its origin to a German naturalist, Dr. Dohrn; and the German booksellers have contributed to it a library worth about 1,500*l*. The English naturalists, headed by Mr. Darwin, have also testified their interest in this novel scientific enterprise by a contribution of 1,000*l*. to its funds.

DARK ROOMS MADE LIGHT.—Chappuis' Patent Reflectors are used to reflect the daylight, and do away with gas during the day time, thus saving expense and ministering to both health and comfort. They can be adapted wherever there is either window, skylight, fanlight, area, grating, or any communication with the outward daylight. These reflectors are made of crystal surfaces, corrugated or shaped according to scientific principles, and coated with deposits of pure silver, also of silver-plated metal, rendered water and air-tight and fitted in well-constructed frames of different shapes and sizes as required. Being fixed outside windows or under skylights, they reflect the daylight rays and diffuse them in all places or apartments where the natural light is insufficient, owing to the small size of windows or the proximity of walls, houses, etc. Mr. Chappuis' patents are patronised by H. M. Commissioners of Works, the Royal Engineers, the Admiralty, all leading architects, contractors, bankers, merchants, manufacturers, etc.; they are also in general use for private houses, institutions, etc., upwards of twenty thousand having been supplied since 1851. The reflectors may be seen in operation and prospectuses obtained at the manufactory, No. 69 Fleet Street.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 1*7s*. 4*d*.; free by post, 1*9s*. 6*d*.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s*. 6*d*. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre — Leipzig: Mr. K. F. KOEHLER — Florence: Mr. E. LOESCHER — Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 1*9s*. 6*d*. Cloth Cases for binding the Numbers for each year may be had for 1*s*. 6*d*. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

WEDNESDAY, FEBRUARY 24, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BOWDITCH ON RECENT RESEARCHES ON VASO-MOTOR NERVES.*

One of the most important recent advances in our knowledge of the physiology of the circulation is the distinct recognition of the existence of a class of nerve-fibres, whose function is to *dilate* the vessels to whose muscular walls they are distributed. That vascular dilatation may follow the stimulation of a nerve supplying the vessels under observation, is not a recent discovery. The fact that irritation of the chorda tympani produces vascular dilatation and increased secretion in the submaxillary gland was observed by Bernard as long ago as 1858; but it is only within a few years that the cause of this dilatation has been shown not to lie in the increased glandular activity. This point may be regarded as having been settled by the experiments of Heidenhain,† who found that, on a dog under the influence of atropine, irritation of the chorda tympani caused no increased salivary secretion, though the vascular dilatation took place as usual.

For a long time the fibres of the chorda tympani in the submaxillary gland and the nervi erigentes distributed to the corpora cavernosa penis, as described by Eckhard‡ and Lovén||, were regarded as the only nerves possessing the power of producing vascular dilatation in the parts supplied by them, the observations of Bernard, which led him to attribute to the pneumogastric nerve a similar power over the vessels of the kidney, having lacked confirmation.

Dr. Bowditch then summarises the observations of Vulpian on the chorda tympani and lingual nerve (LONDON MEDICAL RECORD, April 30, June 4, November 19, 1873); of Goltz, Putzeys and Tarchanoff (*ibid.*, December 16, 1874); and gives the following theory as an exposition of his views on the subject.

In consideration of all these observations, the most probable view which we can take of the relations between the vaso-motor nerves and the vessels to which they are distributed seems to be the following.

The smooth muscles of the blood-vessels are kept in a state of moderate tonic contraction, under the influence of a plexus of nerve-fibres and ganglion-cells closely surrounding and imbedded in the vascular walls.§ This tonic contraction is increased by an impulse coming from the central nervous system through the 'vaso-constrictor' nerves.

That these 'vaso-constrictor' nerves are in a state of constant activity, is evident from the fact

that vascular dilatation follows their section (for example, in the cervical sympathetic or sciatic nerves). This vascular dilatation is, however, not permanent. After ten days or a fortnight, the vessels assume their original dimensions. To explain this, we must assume that, after separation from the central nervous system, the nervous plexus surrounding the vessels gradually acquires a higher degree of activity than it possessed before. A justification of this hypothesis is found in the analogous observation, that the reflex centres in the spinal cord acquire a greater irritability after their separation from the brain by a section in the cervical region.

The 'vaso-dilator' nerves act by inhibiting the activity of the ganglion-cells in the nervous plexus around the vessels, thus causing a diminution of the vascular tonicity. These nerves are not in a state of continual activity, as is proved by the failure of the vessels to contract when the nerves are divided.* They are to be regarded, therefore, not as constant but as occasional antagonists of the 'vaso-constrictor' nerves.

According to this theory, there is an evident analogy between the muscular walls of the blood-vessels and the heart. In both, the conditions of activity are contained in the organs themselves; and in both, influences derived from the central nervous system may either increase or diminish this activity, the vagus nerve being analogous to the vaso-dilators, and the 'accelerator' nerve to the vaso-constrictors.

It will be noticed that this theory affords no explanation of the observation of Goltz on the effect of a second section of the sciatic nerve on the temperature of the limb. Should this observation be confirmed, some modification of the above theory will be necessary.

ON ARTIFICIAL SALT BATHS (SOOLBÄDER).

BY DR. G. SIEGMUND.†

The object of this paper, by Dr. G. Siegmund, published in the *Berliner Klinische Wochenschrift*, January 11 and 18, 1875, is not to explain what operation the various ingredients of salt springs have on the organism, but to show how the use of salt baths may be introduced into every house. Salt springs, which are obtained from various sources (from natural wells, from borings, from rocks, by letting in water to dissolve the salt they contain) not only differ from each other very much in their degree of concentration, but they often vary in the amount of their mineral ingredients in the same source. Natural springs, and those got by boring may, according to the nature of the rock which is superimposed, be greatly influenced by the daily rainfall. Such natural dilutions are easily made up for by adding a suitable amount of salt; and it would not be necessary to allude to this, if such deficiencies were always attended to in bathing establishments. Whoever has often been present at the filling of baths in such places, must know how little attention is paid to the degree of concentration. But the principle should be laid down, that the degree of concentration ordered by the medical man, should be as much attended to, as the degree of temperature. The quantity of salts present in the waters of the most visited baths, varies from about 1·5 to 31 per

cent. (Rheinfelden) or to the strength almost of a saturated solution; and if we consider only the amount of chloride of sodium, those having less than 1 per cent. are scarcely worth counting, while the stronger ones reach 20 and even over 30 per cent.

But we must guard against considering the strength of the natural water as identical with the strength of the bath, and here attention must be called to a fault from which few monographs are free, not even Dr. Niebergall's careful tables in Valentiner's *Balneology*, 1873. Handbooks, and special accounts of baths, give analyses of salt springs; but as there are but few salt springs whose waters are used in their natural state, most salt waters are, in fact, constantly either strengthened or weakened, according to their degree of concentration. It is not enough to tell us how much is added to a bath, unless we are told what the whole quantity of water in it is. The quantity of water added to reduce a concentrated solution, and the quantity of a weak salt water to which a certain amount of the concentrated solution is added, must both be known. But from neglect of this, we generally are ignorant of the real strength of a bath, and in many places can only ascertain it by the use of a hydrometer. We imagine a strongly concentrated fluid, when we think of the Ischl spring, containing 24·5 per cent. of salts, and of a bucketful of it containing thirty to thirty-three pounds, and know that one or two bucketsful are added to the bath. But if we reflect that a full bath requires about fifteen bucketsful of water to fill it, we find that the addition of one bucketful only brings the bath water up to the strength of a salt spring of the second degree, and of two buckets to that of one of the third degree; and in Arnstadt, where the natural spring contains from 22 to 25 per cent. of salt, although, according to Niebergall, baths are occasionally prepared of the strength of 8 per cent, yet the usual strength is only for children from 1 to 2 per cent., and for grown-up people 3 per cent.

The actual practice at different baths varies much, and depends much on the abundance or otherwise of the supply of salt. If in Ischl the baths seldom exceed 3 per cent., and in Kösen the baths of nearly 5 per cent. are counted strong and exciting, no one thinks anything of the nearly 5 per cent. water of Colberg. In Salzungen the strength is usually from 3 to 6 per cent., and this is often further fortified by the addition of mother-liquor, as it is called. The baths in Rheinfelden are of a strength of 3 to 8 per cent., and in Frankenhausen of 7 to 8 per cent. and more; yet the patients do not complain of excitement, sleeplessness, or of irritation of the skin, or of any other unpleasant effect. We are wont to think only of the chloride of sodium in salt springs; and indeed the other constituents amount to a very small quantity, as is apparent from the following table. (*See next column.*)

This table shows sufficiently the immense preponderance of common salt. There are, however, some exceptions to this rule: thus, in the Hubertusbad, the total of mineral ingredients is 2·69 per cent.; of this only 1·49 is chloride of sodium, while 1·16 is chloride of calcium, and in a well in Suderode the chloride of calcium, 1·5 per cent., exceeds the chloride of sodium, 1·1 per cent. In Zaizon, one of the iodine and bromine springs, in 0·27 of mineral ingredients 0·06 is the amount of chloride of sodium, 0·02 of iodide of sodium. Similar exceptions might be adduced, but the general rule of the entire preponderance of chloride of sodium over other con-

stituents remains unaffected. With reference to the occurrence of other salts, there is no uniformity. Besides sulphate of lime, which is rarely absent

(and which is of no great therapeutic importance), sulphate of soda and of magnesia occur, but by no means constantly, and only in small quantity.

Passing by iodine and bromine, which do not bear directly on our object, the remaining salts are combinations of chlorine and alkalis. Of these chloride of magnesium is usually present; chloride of lime and chloride of potass are so occasionally.

I must next speak, Dr. Siegmund says, of the practice prevailing almost everywhere of strengthening the baths with the mother liquors.

Here, too, there is no rule as regards the chemical mixture. Iodine and bromine, referred to with much pride in some mother-liquors, are entirely wanting in others, and when they are present, what amount of real efficiency do they possess? In the lye of Münster, according to one analysis, we have 0·59 per cent. of bromide of sodium and 0·05 of iodide of sodium; according to another one, we have 0·6 of the bromide without any iodide, while another gives the Theodorshall spring 0·77 of bromide of sodium and 0·0007 of iodide of sodium. We may then have in those two lyes, 0·6 to 0·7 of the bromides and iodides.

Suppose we add, what is counted a large quantity, 10,000 grammes of the lyes to a bath containing 300 litres, we have about sixty grammes of bromine and iodine compounds, or perhaps 0·02 per cent. It may be possible, that even with this degree of dilution there may be, in the presence of the other salts of the solution, some slight cutaneous absorption; but we must remember that the above strength is greater than that of the baths usually supplied.

Where bromine and iodine are absent, it is generally the presence of a large amount of chloride of calcium that is characteristic—for instance, in Nauheim 29·97 per cent., in Münster about 25 per cent., in Theodorshall 33·2 per cent.; but in some places chloride of magnesium is in excess in the lye, for instance, 48·6 of chloride of magnesium against 23·9 of calcium in Wittekind, and 24·4 of the former against 17·06 of the latter in Arnstadt. In Salzungen there is 17·2 per cent. of chloride of magnesium and none of calcium, and in Ischl and Rheinfeld the lye is practically only a very rich solution of common salt, with perhaps a tenth of other chlorine compounds which are soluble in the lye.

The great dissimilarity of the composition of the salt springs naturally repeats itself in the lyes. It is out of the question to talk of them as homogeneous fluids; and even if their constituents were well ascertained, and their variations were closely copied in

their imitations made at Leopoldshall, yet it is beyond doubt, that physicians order lyes quite promiscuously, those of Colberg, Schonebeck, Salzung, Wittekind, as they may be nearest to hand, and that they only use them with more discrimination, perhaps, in the case of those valued for containing iodine or bromine.

We may draw one general conclusion from all this, that we do not act under the guidance of any principle. We do not know what is the special action of the chloride of sodium, or that of the other salts. Our only criterion is the amount of salts; we know that a certain degree of concentration is necessary to produce a certain stimulation of the skin.

As examples of the absolute amount of salts in individual baths, we may further mention, that the water of Elmen contains sixty pounds of salts in a bath of thirty cubic feet; that of Salzungen, in the bath (the amount of the water of which is not given), forty to forty-eight pounds; and that of Frankenhäusen forty-eight pounds in only 300 litres of water.

We shall next inquire what course has been usually pursued in the preparation of artificial salt baths as compared with natural ones. We make use of sea-salt, seldom of chloride of sodium, or of mother-lye or its salt, to strengthen the salt baths. But in what quantities do we use them? The quantity of sea-salt or of chloride of sodium for a bath is usually set down in handbooks at two to six pounds. The *Prussian Medical Calendar* of 1874 was the first to say from ten to fifteen pounds. Now the former maximum of six pounds, which even now is counted a considerable quantity, gives in a bath of 300 litres a solution of 1 per cent. An idea may be got of how little conception people had of the real strength of such baths, from the fact that patients in hospitals here when ordered salt baths, usually were ordered not more than six baths, each of which contained 2 lbs. of salt. But the uselessness of the ordinary practice is still more apparent in the case of the mother-lyes. It was usual to order 1 to 2 lbs. for a child's bath. Usually the lye was selected with reference to the quantity of iodine which it contained; but had one any right to expect important results from so small a quantity? The Kreuznach lye, the most popular of all, contains in 500 grammes about 3 of iodine and bromine compounds. The smallest baths used contained 50 litres or 100 lbs., = 50,000 grammes; the 3 grammes added to this gives a proportion of 0.006 of iodine and bromine compounds. Grown-up people no doubt were ordered 1 or even 2 litres; but in a bath containing 200 to 300 litres, the dilution was still greater. And if we must now admit that the ordering such small quantities in private practice was in fact a sham ordering, what is the justification for using mother-lyes at all? It seems really to have been the result of following an ancient, somewhat mystical belief in the action of salts, without reference to the quantity in which they were present. In imitating natural salt baths, we are thus constantly ridiculously behind our originals. The grounds of this are two: first, if we are to tell the truth, the carelessness of the physicians, who had forgotten to calculate the proportion of salts necessary; and, secondly, the increasing dearness of the materials of the bath. We are thus brought to face the fact, that our country is rich in a material which is easily procured, yet is proscribed from common use by artificial circumstances, and especially by taxation.

In the hopes of getting the tax taken off salt that

was to be applied to bathing purposes, I applied to the minister of commerce, and asked whether the rough salt which, as supplied to chemical works, pays only a small duty, might not be subject to an equally low rate of tax when supplied for baths; but there were financial difficulties in the way, and the minister obligingly called my attention to the so-called Stassfurt bath salt.

This is a rich potash salt, which is found in a natural state in Stassfurt; its average constitution is as follows:

	Per cent.
Chloride of potassium	16.8
Chloride of magnesium	26.5
Chloride of sodium	13.6
Sulphate of magnesia	11.6
Water, etc.	31.6
Total	100.0

It will be observed that there is not much chloride of sodium here. Other chlorine compounds predominate, especially chloride of magnesium, and the composition resembles that of a mother-lye rather than of a salt spring; nor does it strongly resemble the saline contents of the water. The water of the Atlantic Ocean contains nearly three and a-half per cent. of salts, which consist of

	Per cent.
Chloride of sodium	76.05
Chloride of magnesium	9.0
Chloride of potassium	4.0
Bromide of sodium	1.15
Sulphate of lime	4.60
Sulphate of magnesia	5.20
Total	100.0

Notwithstanding its difference of composition from salt springs or sea water, the Stassfurt salt is coming every day into more extended use; and I have myself frequently used it up to the strength of 4 per cent. and with exactly the same effect as salt baths of the same strength.

Its great advantage is its cheapness; 1 lb. costs only about two pfennigs (one-fifth of a penny); it therefore can readily be employed in poor-houses and hospitals. But we must be more accurate for the future in ascertaining the exact strength of the baths supplied. For all ordinary purposes it is enough to imitate the strength of the weaker salt springs or of the ocean, and give a bath containing from 1 to 4 per cent. of salt. For the earlier ages from 1 to 2½ per cent. is strong enough. For adults, unless under special circumstances, it should not be weaker than 3 per cent. Calculating the amount of water, a child's bath requires from 1 to 2 lbs. of the salt; an adult's, 12½ to 16½ lbs. The rich have usually larger baths, and may require 48 lbs.

But another kind of salt also occurs at Stassfurt, containing a larger quantity of chloride of sodium; its chemical composition is as follows, according at least to the latest analysis of it.

	Per cent.
Chloride of sodium	43.0
Chloride of potassium	9.4
Chloride of magnesium	12.8
Sulphate of magnesia	15.6
Sulphate of lime	1.5
Water	17.7
Total	100.0

Viewed chemically, this compound comes nearer sea-salt and various mother-lyes, and would therefore seem better adapted for our purpose; but, practically, a portion of the salt is not only very insoluble,

but it swells before it dissolves. Possibly these disadvantages may be overcome, and it is to be hoped that they may be so, as this salt is even cheaper than the last-named one.

In any case, there is no longer any difficulty in supplying salt-baths to the poorest patients; and we must have a complete reform of baths of this kind. Their strength can no longer remain a matter of guess work. Their percentage of solids must always be ascertained with a hydrometer. It will also save time in preparing baths, if concentrated solutions of the salts be kept ready, which may be poured at once into the baths, and will prevent the delay of waiting for the solution of the salt, if put in in its solid state. There would be no difficulty in having artificial baths on a large scale, in introducing carbonic acid into the solutions of the salt, and in having inhalation-rooms; and the managers would have their establishments more under control than the proprietors of natural waters have their ones.

No doubt natural salt-baths will always retain the advantages they possess—in locality, in climate, and in amusements; and will continue to be resorted to in summer. But rivalry will lead to their exact composition being more minutely studied; and, indeed, the whole subject of the operations of chlorine compounds on the system requires to be more fully investigated. Possibly other analogous salts might have the same effect.

[Of late years, the exaggeration which has prevailed about the strength of sool-baths, and the fabulous amount of iodine they were supposed to contain, has been pretty well exposed. Dr. Siegmund's paper will help to enforce more precision. In Germany, where sea-bathing is entirely beyond the reach of the mass of the people, sool-baths have always been favourites, and they are growing in popularity. In England salt-baths have been much neglected. Sea-bathing is rarely pursued systematically; and it is only of late that the idea of adding to the strength of sea-water baths has been thought of. Of weak sool-baths, England has Woodhall Spa, tolerably prosperous; Ashby-de-la-Zouche, used a little; and Victoria Spa, we believe, closed. The only strong sool-baths in England are those of Droitwich, to which place and to its new bathing establishment the LONDON MEDICAL RECORD has several times called attention during the last two years.—*Tr.*] J. MACPHERSON, M.D.

DE PIETRA SANTA ON THE PATHOGENESIS OF DISEASES FROM MORBIFIC FERMENTS, AND THEIR TREATMENT BY ALKALINE HYPOSULPHITES AND SULPHITES.

Dr. De Pietra Santa has published, in the *Mouvement Médical*, p. 91, advance sheets of the chapter on medication by sulphites, from the volume which he is about to publish on the rational treatment of pulmonary phthisis (*Le Traitement Rationnel de la Phthisie Pulmonaire*.) He announces that treatment by the alkaline and earthy sulphites has been and will always be fruitful in good results. The experimental researches of Dr. Polli, of Milan, have been conducted with all desirable science and skill. (See Dr. Timermans' report to the Academy of Turin.) These researches of Dr. Polli on diseases from morbidic ferments, and their treatment by alkaline and earthy sulphites and hyposulphites, have given rise to

numerous ideas, writings, and practical applications of the treatment in Italy, England, and Belgium. Dr. De Pietra Santa has thought it his duty, before making public the contingent of facts and observations collected by him during a first period of ten years, to thoroughly determine the theoretic principles of medication by sulphites, and to make known with impartiality the results obtained by a large number of distinguished practitioners. Numerous experiments made on animals with all the guarantees of scientific exactness, have demonstrated that the artificial injection of certain morbidic substances produces serious and well-marked diseases, presenting the characteristics of catalytic affections. 1. The injection of a certain quantity of pus into the blood produces pyæmia, and the affections characterised by multiple of abscesses. 2. The injection of putrid matters produces septicæmia; that is to say, the diseases known under the name of putrid infections, and characterised by the symptoms of gastro-enteric fever. 3. The injection into the blood of materials eliminated by the mucous membranes in certain contagious diseases, as glanders, reproduces the glanderous affection itself. The question then arises, whether the morbidic ferments in the blood of animals can be neutralised, without altering that liquid so as to be irreconcilable with life; since facts and varied experiments lead to the admission of this neutralisation, notwithstanding the doubts of Claude Bernard, who writes that 'neutralisation of ferments is impossible, because, for that purpose, it would be necessary to change the properties of the blood to such an extent that life would no longer be possible.'

By examining the action of sulphurous acid on organic substances, it is easy to become convinced that it is one of the most powerful of the antifermentative agents. It prevents or stops all fermentation of known organic matters, and impedes the putrefactive metamorphoses in the animal tissues and liquids.

Sulphurous acid acts on the fermentative principle, not by decomposing it, like most so-called antiseptic substances, but by simply modifying its molecular aggregation. Its antiseptic action is as powerful as that of arsenious and hydrocyanic acids, without being, like the last, a poisonous substance. The impossibility of administering sulphurous acid either pure or in a gaseous state, or in a watery solution, has led Dr. De Pietra Santa to combine this acid with alkaline or earthy bases, under the form of sulphites of potash, soda, lime, magnesia, etc. These sulphites possess the antifermentative properties of sulphurous acid. Their action is even more constant and more penetrating; and, as they are perfectly tolerated by the living organism, they may be administered internally in medicinal doses, and sometimes in the liquid state. Absorbed by the lacteal vessels and by the veins, the sulphites diffuse themselves throughout the blood-mass, exercising a specific and benign action on the various materials of the blood and on the tissues derived from it, during the whole time indispensable for their complete transformation into sulphates. This transformation, which is produced by the oxidising action of the phenomena of respiration, takes a somewhat long time.

In fact, whilst the sulphites are found again in the urine a few hours after their administration, it is only at the end of twenty-four hours that they are eliminated in the condition of sulphates. To prolong the presence of the sulphites in the organism,

and to retard their conversion into sulphates, when it is desired to protect the blood against the absorption of a morbid ferment, hyposulphites of the same bases must be substituted for sulphites. These hyposulphites require a longer oxidising action to bring them into the condition of sulphates, and they at the same time provide a means of carrying and introducing into the blood very active sulphites in the nascent state. Thus, as a general rule, the sulphites and the hyposulphites which are introduced into the organism pass into the secretions in an always higher degree of oxidation; the hyposulphites as sulphites, the sulphites as sulphates.

The seventy experiments instituted on animals for the purpose of demonstrating the possibility of neutralising the morbid ferment may be divided into three categories,—*A* with pus; *B* with putrefied blood; *C* with glanders. They completely confirmed the principles laid down, whilst furnishing an amount of complementary information, useful in showing with greater certainty the numerous therapeutic applications of this new system of medication. 1. The blood, urine, viscera, and muscles of animals submitted to the daily action of alkaline sulphites, are, after death, less quickly attacked by the phenomena of decomposition and putrefaction. 2. Animals to which a certain quantity of sulphites has been administered resist the morbid action of pus, putrefied blood, and glanders injected into their veins, whilst the same doses of virus produce serious disease and death in animals to which sulphites have not been administered. 3. Animals submitted to the injection of putrid matters (pus or putrefied blood), into whose veins a solution of alkaline sulphite is immediately afterwards injected, resist infection or recover in a few days; whilst other animals, placed in identical conditions, but without the sulphites, succumb to typhoid fever. 4. The same animal which has undergone putrid injection without any serious accidents, because it had previously been submitted to the action of sulphites, becomes seriously disordered or dies, if it receive a fresh injection of the same quantity of putrid matter without having been sulphitised. 5. In animals inoculated with the mucus of glanders, and treated before or after the operation with sulphites, even when the resulting wound is converted into the characteristic sore of glanders, a sensible modification of the sore is noticed, followed by cicatrisation. The same inoculation of glanderous mucus in other animals not subjected to the influence of sulphites, produces, *in situ*, a phlegmon which kills in a few hours, or a general infection with multiple abscesses leading to marasmus and death.

It now becomes a question, to which alkaline salts the preference should be given. The sulphite of magnesia in the solid state is easily administered internally. The sulphite of soda, which effloresces readily on contact with the air, possesses a very marked odour of sulphurous acid; very soluble in water, it is better in fresh solutions for dressings, lotions, or external fomentations. As the sulphites of potash and ammonia have a very disagreeable flavour, and change very easily, they should be reserved for the external treatment of certain sores of a malignant nature.

The hyposulphite of soda may in many cases be substituted for sulphite of magnesia. It is very soluble, and its flavour is very tolerable; its most logical indication is as a prophylactic. As it contains more sulphur, it furnishes, under the influence of the

action of the respiratory organs, sulphite of soda in the nascent state in the heart itself.

The hyposulphite of lime, which has not a disagreeable taste and keeps well, is specially indicated when it is desirable to protect the organism against the effect of purulent absorption, or to favour calca-reous deposit and obliteration.

It is, however, in the class of diseases arising from purulent absorption that the most strongly marked therapeutic results should be found, because in them are found conditions of genesis analogous to those which were shown in experiments on animals.

Drs. Sestini and Ferrini, of Turin, have administered the hyposulphite of lime with success in several cases of tuberculosis in the third stage, with nocturnal fever and abundant and foetid expectoration. Polli has already made an important series of observations, which all tend to demonstrate the serious modifications in the augmentation of the general vitality, which take place in the nature and quality of the matters expectorated in the height of hectic fever. In each case, the diagnosis of the disease is established on the general symptoms and on the direct signs of the anatomical change furnished by auscultation and percussion. Dr. Rodolfi says that with the sulphites of magnesia he has been able on several occasions to combat violent attacks of fever with shiverings, in tuberculous patients arrived at the third stage, when this fever of consumption had been treated without success by preparations of quinine. Brunetti, of Constantinople, combats zymosis of the respiratory passages by preparations of sulphite of soda and hyposulphite of lime.

Zalloni and Parascheva, of Syra, congratulate themselves on having been the first to employ sulphites of soda, which have yielded surprising results at the commencement of tuberculosis. Dr. De Pietra Santa states that he has seen the excellent effects of hyposulphite of lime on the second and third stages of pulmonary phthisis. It is well known that in this terrible disease there is a time, in the cavernous stage, when the treatment can only aim at patching up certain morbid phenomena and prolonging the life of the patient. At that time, the pus which is not entirely eliminated by expectoration is absorbed into the organism; and this purulent infection is shown by the nocturnal fever, the diphtheritic irritation of the buccal and gastro-enteric mucous membrane, the colliquative diarrhoea, the nocturnal sweats, and the general emaciation. To prevent this decomposition of pulmonary tissue and to combat the putrid absorption, logic bids us have recourse to therapeutic agents capable, first, of protecting the blood against the catalytic action of the pus which penetrates into the circulatory torrent; secondly, of thus diminishing the purulent exudation in the pulmonary cavities.

It is here that clinical observation has stepped in to demonstrate that alkaline hyposulphites are perfectly indicated to prevent this general decomposition; to arrest the deleterious action engendered by the purulent focus in the blood; to moderate the partial phlogoses of the pulmonary tissue; and, finally, to induce the phenomena of deoxidation. By protecting the blood against the catalytic action of the pus which penetrates into the circulatory torrent, they diminish by so much the purulent exudation in the pulmonary cavities.

As to the hyposulphite of lime, independently of the qualities which it shares with the salts, its congeners, it offers a certain and convenient means of

introducing lime into the body, with the effect of favouring the transformation of tuberculous into cretaceous or plastic matter. This salt, the hyposulphite of lime, penetrating into the blood, thus fulfils the double indication of opposing itself to the effects of purulent absorption, and of effecting a calcareous saturation of the organism. The hyposulphite of lime, associated with the phosphate of iron, is indicated when complications of the phenomena of dysmenorrhœa, chlorosis and general weakness, are met with.

ON CATARRH OF THE SMALL INTESTINE IN CHILDREN. BY DR. ALOIS MONTI, OF VIENNA.*

Catarrh of the small intestine is one of the most frequent diseases of childhood. In the children's department under my care in the general polyclinic of Vienna, I have had 208 cases of this malady during 1872 and 1873. Of these, 117 were males and 91 females.

Intestinal catarrh mostly affects children during the first two years of life; although it may occur beyond that age. The majority of cases (105) occurred within the first year; there were sixty-one cases between the ages of one and two years; and twenty-six at the age of two; beyond this age, the number in each year rapidly diminished.†

The explanation of this lies, in the first year, chiefly in the special character of the food (milk), and between the ages of one and two years both in the change of food and in the simultaneous gradual development of the intestinal tract (stronger development of the intestinal glands and muscles, etc.)

The greater proportion of cases (106) occurred during the summer months, from June to September.‡

Among the causes of catarrh of the small intestine, artificial feeding plays the principal part. Of the 208 cases, in 160 the disease could only be attributed to this cause. It would be tedious to enter into all the particulars in this respect. Suffice it to say that the younger the children were, the greater was the number of cases due to artificial feeding, and, I might add, the more rapidly did its mischievous influence show itself. Intestinal catarrh came under observation as a result of all possible methods of artificial feeding, good and bad; and the more the food differed from the natural nourishment, the more frequently intestinal catarrh and its results appeared. Among the most injurious forms of artificial food were, bad cow's milk; milk excessively diluted or with too great an addition of sugar, or with the addition of articles difficult of digestion, such as rice-water, fennel-water, Indian corn, etc.; the administra-

tion of amylaceous food at too early a period or in too great quantity; and the excessive dilution of condensed milk. Even with the use of Liebig's soup, or its substitutes (Löflund's food for children, etc.), diarrhœa frequently occurred, but much more rarely than under the conditions just mentioned. The same remark is applicable to Nestle's food. The feeding of children with meat-broths must also be mentioned here as capable of producing diarrhœa, if such food be given to children when too young, or if they be fed exclusively on it. Meat also, given to children too early, or in improper form and quantity, leads to intestinal catarrh.

In children fed by breast, the disease is not so frequent as in artificially fed children; of the 208 cases, only twenty-one occurred in breast-fed infants. Among these, the overfeeding of the children, through the too frequent application of the breast and immoderate suckling, was the most frequent cause of intestinal catarrh. Here also must be mentioned a condition of milk not suitable to the age of the child, a too diluted or imperfectly digestible milk, especially in wet-nurses, the time of whose confinement differs too much from that of the birth of the children entrusted to them. As a general rule, all causes capable of producing dyspepsia may, if continued long enough, lead to diarrhœa. In some cases, I found that the suckling of the child beyond the normal period of nine months must be reckoned among the causes of intestinal catarrh.

That children fed on a mixed diet of human milk and other food, such as milk, coffee, starches, broth, meat, etc., very frequently suffer from diarrhœa, is a well-known fact.

In ten cases, weaning was to be regarded as the cause of intestinal catarrh; generally it was too sudden, while in other cases it was too early. After weaning, the choice of food is of great importance; and a sudden transition from fluid and homogeneous food, such as mother's or nurse's milk, to a more consistent food, very often proves injurious.

Besides the above-mentioned causes, an important part is frequently played by errors in diet, either through too abundant feeding, or through the use of articles of food not suited to the age of the child.

In not a single case could I attribute the intestinal catarrh to cold; nor was I able to connect its occurrence with the process of dentition.

The frequent occurrence of chronic intestinal catarrh in rickety children is remarkable; of the 208 cases, 44 belonged to this category. This supports Löschner's view, that rickets is to be regarded as a result of chronic intestinal catarrh. The occurrence of catarrh of the small intestine was also often observed in children suffering from chronic skin-diseases, such as eczema, prurigo, pemphigus, etc. Scrofulous children, whether the lymphatic glands be principally diseased, or whether they have periostitis, ostitis, or chronic disease of the joints, are, according to my experience, very frequently affected with intestinal catarrh.

Symptoms.—The most important symptom is the diarrhœa; for it affords very valuable and characteristic diagnostic indications. Defecation is preceded by premonitory signs, especially intense colicky pains. Small children become restless before each stool; they begin to cry very violently, and for a long time; they draw up the thigh on the belly, urge constantly, and refuse all food. The attacks of colic last for a longer or shorter time, and

* From the author's 'Pædiatric Contributions,' about to be published, *Wiener Medizinische Wochenschrift*, nos. 1 et seq., 1875.

† The following were the numbers at the various ages. Under 1 month, 5 cases; 1 month old, 7; 2 months, 9; 3 months, 21; 4 months, 9; 5 months, 7; 6 months, 15; 7 months, 4; 8 months, 5; 9 months, 7; 10 months, 5; 11 months, 3; 12 months, 8; 13 months, 5; 14 months, 8; 15 months, 15; 16 months, 6; 17 months, 10; 18 months, 5; 19 months, 6; 20 months, 3; 21 months, 3; 2 years, 26; 3 years, 5; 4 years, 2; 5 years, 3; 6 years, 2; 7 years, 2; 9 years, 1; 12 years, 1.

‡ The distribution of the 208 cases in the several months was as follows:—January, 5; February, 1; March, 9; April, 24; May, 11; June, 15; July, 30; August, 41; September, 20; October 17; November, 17; December, 18.

pass off after defæcation. The stools are more or less frequent, according to the intensity of the disease; and a characteristic of them is, that the single defæcations are very abundant in quantity. The defæcation is accompanied with a discharge of gases, and is attended with noise, as the contents of the intestine are expelled as from a clyster-pipe. The consistence of the stools is much diminished; according to the intensity of the process they are soft, thickly fluid, or as thin as water. The colour of the dejecta are always changed; in children, under one year, they have a pale, yellowish, or even greenish colour; their smell is sour or fæcal; in slighter cases the reaction is feebly or strongly acid, in the more severe forms of the disease it is neutral. A characteristic phenomenon was found to be the predominance of the watery over the solid constituents; and the more intense the disease was, the greater was the increase in the proportion of water.

In cases where the intestinal catarrh developed itself from dyspepsia, detritus of milk was found at the beginning of the disease; the stools contained flocks of casein in a perfectly undigested state. In cases where the intestinal catarrh set in independently, or on the further progress of the disease, the *débris* of milk increased in proportion with the severity of the malady. Mucus was present only in small quantity. In children more than one year old, the discharges were of a greyish, white, brown or green colour, and had an intensely fæcal odour. They consisted of remains of food, with water as their chief constituent.

Another characteristic symptom which I have observed is meteorism. According to the intensity of the disease, the abdomen was more or less distended; and it remained distended in spite of the frequent defæcation; touching it frequently produced pain or gave rise to gurgling sounds.

Another characteristic sign is, that catarrh of the small intestine in children under one year frequently commences, and even passes through its course, without fever. When fever set in in the course of the cases which I observed, it was always due to some complication, such as catarrh of the large intestine, bronchitis, pneumonia, etc. In children, however, who had passed their first year, and also in cases where the catarrh of the small intestine had arisen from errors in diet, or from acute gastric catarrh, fever was sometimes present at the commencement of the malady.

Besides these characteristic phenomena, I also found a series of symptoms which may be observed in other diseases of the intestines. They were the following. Thirst was more or less severe, according to the intensity of the disease. Diminution of the urinary secretion increased with the severity of the malady. In cases of profuse intestinal discharge, there was frequently a reduction of strength; the fontanelles became less tense, and in very severe cases were depressed; the bones of the head were pressed together, and, according to the degree of collapse there was diminished production of heat on the surface; the point of the nose, the upper and lower limbs, became cold; the eyes were sunken, etc. The acid nature of the stools frequently gave rise to erythema, and even to excoriations on the inner surface of the thighs, on the buttocks, and on the genitalia. The frequent occurrence of colicky pains frequently led to the formation of umbilical and inguinal hernia, especially in the chronic forms of the disease. In several cases there were also symptoms of dyspepsia;

of these I shall have to speak further on, under the head of complications.

The course of the disease was in most cases (119) acute; in the remainder (89) chronic. An acute course was frequently observed in children fed at the breast, and in weaned children; also in artificially fed children under three months of age.

The acute cases terminated:

1. In recovery. This result occurred chiefly in children fed by the breast, or in artificially fed children when a natural diet, or at least one resembling it, was given to them. Recovery was attended with the following phenomena. There was first a rapid diminution of the pain and meteorism, with decrease of the thirst and increase of the urinary secretion; then a decrease in the frequency of the stools, which gradually became less in quantity. The diminution of the watery contents and the increase of colouring matter were further indications of commencing recovery. When the stools had regained their normal colour and consistence, recovery might be considered complete. With these phenomena, the nutrition of the child, which was at a standstill during the acute intestinal catarrh, generally increases rapidly. The duration of the disease varied between a few days and two or three weeks. During the course of the acute intestinal catarrh, nutrition was at a standstill in the milder cases, while in the more severe ones emaciation was observed.

2. In catarrh of the large intestine (enteritis). This result was met with especially in those cases where the intestinal catarrh had been neglected at first, or where an unsuitable diet was given after weaning. It occurred most frequently in children between one and two years old; in these, the symptoms of enteritis received a peculiar stamp from the continuance of the catarrh of the small intestines. In several cases this result was attended with fever, either continued or presenting afternoon exacerbations. In another series of cases, the complication now under notice took place without fever. Another symptom which indicates the advent of enteritis, is the sudden decrease of the meteorism and the colic. The stools now occasionally change; sometimes they have the same appearance as in the commencement of the disease, while in other cases they present the characteristic peculiarities of enteritic discharges; they are frequent but scanty; the amount of water is diminished, and they contain a large quantity of mucus. The occurrence of enteritis always indicates a long duration of the illness; it has a tendency to become chronic.

3. The transition to *cholera nostras* was observed chiefly in artificially fed or recently weaned children; and it occurred the more frequently as the result of artificial feeding, the younger the children were. The cholera commences with violent vomiting, and with very frequent, abundant, quite watery, and nearly colourless stools. The abdomen, from having been distended, becomes soft; the colicky pains disappear; and distinct squashing can often be felt on palpation over the abdomen. Along with these symptoms collapse sets in; the fontanelles become depressed, the bones of the head are compressed together, the eyes are weaker, etc. This result of intestinal catarrh is very rare in children above one year old; and I have observed it only after the use of much unripe fruit or of tainted meat.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

ZWEIFEL ON THE DIGESTIVE APPARATUS OF NEWLY BORN CHILDREN.—Zweifel, in a series of researches 'On the Digestive Apparatus of Newly born Children,' (pamphlet, Berlin, 1874, pp. 47, abstract in *Centralblatt für die Medicin. Wissenschaften*, no. 59, 1874), carefully investigated the bodies of newly born children, or those a few weeks old.

Salivary Glands.—Parotid and submaxillary glands were extracted, either simply with water or after Von Wittich's method. The parotid extract always changed starch rapidly into sugar, as was proved by Trommer's and the fermentation tests, and by the polariscope. All experiments with extract of the submaxillary glands on the contrary gave only negative results—a very striking phenomenon in relation to the condition of these glands in the adult. The ordinary diseases of children (diarrhoea, vomiting, etc.) produced no essential change, only the fermentative action was less and slower. On the contrary, this action appears to be absent during the foetal period till near its termination.

Stomach.—The whole organ was finely chopped up, and extracted with water, and hydrochloric acid added to the filtrate to the extent of one per 1,000; in many cases also the glycerine extract of the stomach was used. As the test, well-washed fibrin and casein as free from fat as possible were employed. In all cases there was a tolerably large production of peptones, not far behind that produced by an adult stomach which was used as a control. On the contrary, in a foetus of six months, the results were negative. Casein proved specially digestible.

Pancreas.—The diastatic ferment is absent from an infusion of this gland up to the end of the first month of life, as shown by Korowin and corroborated by the author. It, however, possesses the property of converting albuminous bodies (casein and fibrin) into peptones, and of splitting up neutral fats. In two cases of diarrhoea, it had also lost this property.

Glycogen was detected by Brücke's method in the liver of a four months' foetus, which was examined a few minutes after the heart had ceased to beat.

Biliary Matters (colouring matter and acids) were found in the intestinal canal of a three months' foetus.

VON WITTICH ON THE LYMPHATICS OF THE LIVER.—Von Wittich (*Centralblatt für die Medicinischen Wissenschaften*, no. 58, 1874), like Sikorski, has been able in the living rabbit to inject from the trachea an exceedingly irregular but narrow-meshed network lying partly in the pleura, partly in the subpleural tissue, and partly in the interstitial pulmonary tissue, and accompanying the blood-vessels; the author regards this network as consisting of lymphatics. In the freshly killed animal, he succeeded in injecting not only this network, but also the intercostal spaces, and even the external thoracic muscles when artificial respiration was performed.

If a rabbit be killed by bleeding, and, whilst artificial movement of the thorax is kept up, there be injected into the trachea, under moderate pressure, a concentrated solution of sulphindigotate of soda, one is struck with the quantity of fluid employed, and with the fact that the whole animal becomes of an intensely blue colour. The skin, the coverings of the eye, the tendons, the muscles, and the abdominal

viscera, all become more or less blue, just as by injection into the blood. In only two places has Von Wittich been able to follow exactly the blue-coloured channels, viz. in the choroid and in the liver. In both organs the blood-vessels were almost completely empty, or only partially filled with blood. The blue colour of the choroid arises from a blue layer lying around the vessels (Morano's lymph-sheath of the choroidal vessels); in the liver, a fine injected network surrounds the portal vein and the branches of the hepatic vein, from which exceedingly fine, delicate, blue injected processes penetrate into the hepatic lobules between the blood-capillaries and the hepatic cells. Strongly injected vessels, evident to the naked eye, pass from the hilus, run parallel to the large vessels and the bile-ducts, and surround these, their finer branches passing towards the branches of the portal vein, but the author observed no direct communication between these and the perivascular network. These vessels are not to be confounded with the blood- or bile-capillaries, and Von Wittich can only recognise them as lymph-capillaries. Further particulars as to the method employed are promised.

THOMA ON THE CEMENT-SUBSTANCE OF EPITHELIUM.—R. Thoma (*Centralblatt für die Medicin. Wissenschaften*, no. 2, 1875), in studying the physiological and pathological changes in the epithelium of the frog's tongue, discovered a method by which in the living animal an excretion of indigo in the cement-substance of the above organ, as well as in certain parts of the alveolar mucous membranes, could be produced. This cement-substance appears as a fine deep-blue coloured network, stretching regularly over the whole tongue, between the colourless epithelial cells, and lying somewhat below the level of the free epithelial surface.

The method is the following. A solution of pure sulphindigotate of soda is prepared by diluting, with an equal volume of distilled water, a saturated and filtered watery solution of indigo. This is injected, under a constant pressure, into the median abdominal vein of a frog, so that in the course of two to four hours, from four to six cubic millimetres of the indigo solution are introduced into the body of a medium-sized *Rana temporaria* or *esculenta*. Simultaneously the tongue is irrigated by a 1.5 per cent. solution of chloride of sodium, in consequence of which pronounced widening of the vessels occurs, specially in the arteries, together with great acceleration in the blood-current (LONDON MEDICAL RECORD, Dec. 30, 1874). The microscope shows that the blood is coloured slightly blue. After a short time the connective tissue becomes blue, whilst the muscular fibres and epithelium show no obvious coloration. It is only after two or three hours that the cement-substance shows a deep-blue coloration.

WM. STIRLING, D.Sc., M.B., Edinburgh.

PATHOLOGY.

BIROT ON PATHOLOGICAL ALBUMENS.—M. Béchamp has shown that there are several distinct kinds of physiological albumens. To separate them, he used a method based on the facts that some of them are precipitated by extract of lead, others by ammoniacal extract of lead, and that among the latter are some which remain soluble in

water after they have been precipitated by alcohol from their solution. To characterise them, he determined their rotatory power, their point of coagulation, and their function.

M. Birot has recently studied pathological albumens in the same way, in M. Béchamp's laboratory (*Comptes Rendus*, December 21). These, like the physiological, are divisible into two groups; the first group containing matters for which the name of albumens may be reserved. They are without action on starch, and become insoluble in water after they have been precipitated by alcohol. They are subdivided into (1) those which are precipitated by extract of lead, and (2) those precipitated by ammoniacal extract of lead. The second group contains albuminoid matters, to which, from their special action on starch, and their function of soluble ferment, M. Béchamp gives the name of zymases. They remain soluble in water after precipitation by alcohol. They are distinguished by the intensity of their action, and by their rotatory power. Liquids from pleuritic effusions, ascites, hydrocele, cysts, etc., have generally yielded the albumens of the two sub-groups and a zymase. The albuminoid matters isolated were essentially distinct also in most of their physical characters, in their points of coagulation, and in the aspect of their plumbic combination. M. Birot gives a number of figures relating to these characters, and they differ so considerably as to justify the view that the albumens obtained are definite compounds.

Comparing his results with those got by M. Béchamp in the case of blood, he concludes that his albumens are different. Thus no albumen isolated by him (M. Birot) had the rotatory power of the albumen of blood which M. Béchamp isolated; and, while the zymase of blood exists only in small quantity, and fluidifies starch very slowly without saccharifying it, pathological zymases are much more abundant, and sometimes saccharify starch quickly.

In view of the difference between albumens of pathological liquids and those of the blood, M. Birot considers that, even in mechanical effusions, the albumens of the serum are altered as they transude. The tissues, indeed, are living and active, and cannot be compared to inert filters. They themselves secrete albumens, or modify those passing through them. These different actions depend both on the proper nature of the tissue and on the influence to which it is subject; it is thus that the pleura does not transform albumens of serum as the peritoneum does. The albumens also are different in the pathological liquids secreted by the same individual, if the analysis be made at an interval of a few days.

M. Birot insists on the constant presence of a zymase. Before M. Béchamp, these substances were not distinguished from other albuminoid matters in the system, so that certain authors attributed to all albumens a property (that of saccharifying fecula), which is special to zymases. No zymase from a pathological liquid was capable of transforming cane-sugar into glucose.

In analysis of albuminous liquids, especially urine, it is necessary to take account of the zymases; the increase of nepozymase in this liquid may be such (the author has found), that it constitutes a veritable albuminuria, which might be called zymasuria.

All the ordinary methods (M. Birot says) of deter-

mining albumens are faulty. The only accurate method is that suggested by M. Béchamp; it consists in precipitating one volume of the liquid by three volumes, at least, of alcohol at 90°. The precipitate is then analysed, to ascertain the presence of a zymase, and to give account of the mineral matters precipitated.

M. Birot makes some remarks on the buffy coat which often forms on albuminous liquids. This is quite comparable to fibrine. Under the microscope, it is resolved into a mass of microzymes; it is they that produce it. In fact, if the liquid of ascites, etc., be filtered several times so as to remove the microzymes which swim in it, the formation of a buffy coat is prevented; whereas the same liquid, unfiltered, gathers into a mass, and in the surrounding liquid there are no longer any microzymes. If the buff be brought into contact with creasotised starch, this is rapidly fluidified, and a true fermentation takes place; the buff is dissociated in this medium. The microzymes are evolved, and transformed into chaplets of granules, into bacteria and bacteridia.

Albuminoid matters are, of themselves, inalterable, when they are pure; that is, when they do not contain organisms capable of living on them and so transforming them.

MEDICINE.

BALFOUR ON THE TREATMENT OF AORTIC REGURGITATION.—The *Edinburgh Medical Journal* for February contains an instructive paper on incompetence of the aortic valves by Dr. G. W. Balfour, physician to the Royal Infirmary. The following is an abstract of some of his remarks on treatment.

In the treatment of a patient suffering from the effects of incompetence of the aortic valves, the first remedy is rest in bed, and in the recumbent position. If orthopnoea be present, it may be safely and advantageously overcome by the use of chloroform, chloral, or morphia, even though there be some amount of oedema or congestion of the lungs; for in the horizontal position the weight of the column of blood which acts on the interior of the ventricle through the imperfect valves is reduced to a minimum; the heart is thus enabled to act more freely, and the pulmonary congestion is soon relieved.

Referring to digitalis, Dr. Balfour says that it is still regarded by many as being not merely useless, but positively dangerous, in cases of aortic regurgitation; yet in his opinion there is no other disease in which this drug is of more value, or in which its curative action can be more efficiently demonstrated. The useful employment of digitalis in aortic incompetence is merely a question of dosage; and in a few years we shall be able to regulate it with much greater nicety than at present. What we desire to produce in each case, is just such an amount of tonic contraction of the ventricle as shall rather more than counterbalance the dilating power of the arterial column. Dr. Balfour prefers the tincture to the infusion, as being more uniform in strength; he orders in ordinary cases from five to ten minims of the tincture every four hours, but he has occasionally given from fifteen to thirty minims every four hours, with great advantage to the patient: with these large doses, however, the pulse must be carefully watched, and if it begin to thump or to falter, or if the

patient complain of nausea on movement, the remedy must be discontinued. With care in thus adapting the dose to the circumstances and idiosyncrasy of the patient, Dr. Balfour has never found digitalis productive of anything but relief, and a relief unattainable by any other means known to him.

J. W. LANGMORE, M.D.

SURGERY.

TILLMANN'S ON DISLOCATIONS AT THE WRIST JOINT.—Dr. Tillmans, of Leipsic, having had his attention directed by Professor Thiersch to a case of old compound dislocation of the lower extremity of the ulna, which required amputation in the fore-arm, was induced to study the literature of this lesion, and to collect from such clinical records as were accessible as many cases as could be found. He has also included in his contribution (*Statische Beiträge zur Lehre von den Luxationen*) collected and tabulated cases of dislocations of the radio-carpal and the carpo-carpal joints, and of single carpal bones.

According to Goyrand, subluxation of the lower extremity of the ulna over the triangular cartilage occurs not unfrequently in children, in consequence of forcible traction on a pronated hand, as in lifting up a child by the hand, or lifting it up by a tug when it is on the point of falling through a false step. The following are the symptoms of this supposed lesion. At the moment when the little patient is pulled or raised by the hand, the person thus acting experiences a grating sound at the held wrist; the child screams, and the fore-arm falls suddenly as if paralysed; the hand is fixed in the pronate position and remains useless. This form of dislocation seems to occur almost exclusively in children. According to Goyrand, it cannot well be confounded with dislocation of the lower end of the ulna backwards, since in the latter lesion the capitulum is very prominent on the dorsum of the hand, the transverse measurement of the wrist is diminished, and the antero-posterior measurement considerably increased. The views of Goyrand as to subluxation of the lower extremity of the ulna have not been favourably received by German surgeons, and the symptoms sometimes produced by violent tugging at a child's hand have been regarded as indicative of injury to the elbow, not the wrist. Tillmans, however, seems disposed to accept Goyrand's statements as to the existence and occasional occurrence of such a form of dislocation of the ulna, and holds that, on account of their support from sure anatomical facts, they deserve more attention than they have hitherto received.

Of complete dislocation at the radio-ulnar joint Tillmans has collected fifty cases, in two of which, however, the displacement was not strictly of traumatic origin. In sixteen of the forty-eight traumatic cases the ulna was dislocated forwards, in eighteen cases backwards, and in nine cases inwards. In the remaining five cases, no mention was made as to the direction of the displacement. Of the sixteen volar or forward dislocations, twelve were simple and four complicated, the complications being, in one case, perforation of the integument; and, in the other three cases, fracture near the lower extremity of the radius with much displacement of the distal fragments. Of the eighteen dorsal or backward

dislocations, ten were simple and eight complicated; in five of the complicated cases the integument was perforated, and in the remaining three cases the radius was fractured. Of the nine inward dislocations of the ulna, eight were complicated; the complications being penetration of the skin alone, fracture of the radius alone, or a combination of these two lesions. From this collection of cases, it appears that the most common form of dislocation at the inferior radio-ulnar articulation is that in which the end of the ulna is displaced backwards with or without fracture of the radius. Tillmans points out that simple dislocation at this joint is not such a very rare lesion as it was supposed to have been by Malgaigne and Cooper. In twenty-three of the fifty cases, the dislocation was of this variety. The rarity of simple inward dislocation of the inferior extremity of the ulna, of which lesion but one case was found recorded, is explained by the fact that this displacement is generally converted by secondary movements into a dorsal or volar dislocation. In the single case of inward dislocation, the lesion was caused through forcible pronation; dislocation of the extremity of the ulna backwards is caused either by forcible pronation or direct violence; dislocation forwards by forcible supination, and also by direct violence. The usual method of reducing every form of radio-ulnar displacement is that of abducting the hand and applying direct pressure to the displaced end of the ulna. Extension was regarded by Malgaigne as not only unnecessary but irrational. In distinct dorsal dislocation supination, and in obstinate volar dislocation pronation, may often be made with advantage. In twenty-one cases (ten volar, eight dorsal, and three inward) there was perfect recovery and restoration of all the movements of the hand, although in seven of these cases the dislocation was compound. In three cases of compound dorsal dislocation, the hand was amputated; in four cases the protruded extremity of the ulna was resected, and in one case the extremities of both ulna and radius. Death followed in three out of the fifty cases, in one from tetanus, in another after gangrene, and in the third from exhaustion after amputation of the hand.

Dislocation of the hand was supposed to be a very frequent injury, until Dupuytren showed that the supposed signs of this lesion were really those of fracture at the lower part of the radius. This surgeon went so far as to assert that complete dislocation of the hand without fracture was impossible. Tillmans, however, found in twenty-four collected cases of traumatic dislocation, fourteen cases in which the hand had been completely displaced without fracture. In eight of these the dislocation of the hand was backwards, and in six forwards. Of the twenty-four cases, thirteen were cases of dorsal fracture, and eleven of volar fracture. Of the thirteen dorsal dislocations three were incomplete, one was complicated by perforation of the integument, and one by fracture of the styloid process of the ulna. Of the eleven volar dislocations, one was incomplete, one was complicated by wound of the integument, and three by fracture of the styloid process of the radius. In ten of the thirteen cases of dorsal dislocation, the hand was replaced by extension and with good results; in one case the lower extremity was resected, in another death was caused through other injuries, and in the thirteenth case purulent infiltration of the whole arm necessitated amputation at the shoulder-joint, which was fatal. Of the cases of

volar dislocation, two were fatal; in one amputation was performed, and in three reduction had not been effected. The more unfavourable prognosis of volar as compared with dorsal dislocation of the hand, is attributed by Tillmanns to the fact that greater violence is necessary to produce the former displacement, and that the soft parts are more extensively and more severely injured.

Traumatic dislocations of the first from the second row of carpal bones, and of single carpal bones, are very rare. Displacement of a single carpal bone is usually caused by direct violence; and, according to Von Pitha, is generally complicated with a lacerated wound. The carpal bones which are most frequently dislocated are the scaphoid, the os magnum, the trapezium, and the semilunar. Tillmanns discusses at some length the interesting injury of dislocation of the os magnum. This bone is always dislocated backwards, and always partially and not completely displaced; the capitulum of the bone only being separated from the articulating surfaces on the scaphoid and semilunar bones. The body of the os magnum is so firmly connected by strong ligaments to the trapezium, unciform, and middle and fourth metacarpal bones, and its articular surfaces are so closely applied to the corresponding articular surfaces of these bones, that an isolated dislocation of this bone forwards could not possibly take place. In consequence of the numerous and strong ligaments of the carpus, but very little, if any, movement can take place between any two applied carpal bones. The only important movement allowed in the carpus is that which takes place between the first and second rows of bones during flexion and extension, abduction and adduction. In movements of flexion and extension, the head of the os magnum moves on its transverse axis in the articular concavity formed for its reception by the scaphoid and semilunar bones; and when the hand is adducted or abducted, it twists around its sagittal or antero-posterior axis. From this allusion to the anatomical configuration of the carpus, it may at once be seen that the os magnum is relatively the most movable bone, and therefore can be most readily detached from the other bones. But this dislocation, when simple, cannot be complete, since the body of the os magnum is so well retained in its place by strong ligaments, and its articular surfaces are so well locked in those of the trapezoid on the one hand, and the unciform on the other. Tillmanns thinks that this incomplete dorsal dislocation of the os magnum is caused by forcible adduction whilst the first row of the carpal bones is fixed; but this view he is unable to support either by clinical observation or by anatomical demonstration.

W. JOHNSON SMITH.

SCHUMACHER ON CONTUSION OR FRACTURE OF THE NECK OF THE THIGH-BONE.—Dr. Schumacher has published the following case.

Joseph B., a well-known thief, was knocked against the door and thrown to the ground in a public-house scuffle. He complained of great pain in the right hip, and as he could not stand, he was removed to the barn, where he remained on the straw all night. He was next day carried home, where Surgeon H. saw him on September 17. He found swelling in the right groin and tenderness on pressure. The patient could take a few steps forward with the help of a stick, but had great pain in his right foot when he did so. Pending the official inquiry no further

examination was made. On September 18, the surgeon again saw his patient, and found him sitting on a bench. The patient could walk three or four steps with the help of a stick, but had great pain, and would allow no further examination of his powers of locomotion. Surgeon H. being otherwise much occupied, and fearing that in this case, as usual, the bone-setter at Laufen would be resorted to, discontinued his attendance.

On September 20, Surgeons H. and B. saw the patient and found the same swelling about the hip, and tenderness on pressure. The skin over the part was black and blue, and covered with the red plaster applied by Surgeon H. Every change in the position of the right thigh gave the patient great pain; and on rotating the limb, crepitation was plainly made out. There was no shortening of any moment. The patient could not stand on the foot of the affected side, nor could he take a few steps forward without very great pain. They diagnosed without hesitation a fracture of the neck of the right thigh-bone. Such an injury was an absolutely severe one, and would require at least six weeks for union; and an additional six weeks would be required before the patient could go about his vocation.

Joseph B. himself subsequently stated that eight days after the receipt of the injury he consulted the bone-setter at Laufen, who reduced (*einrichtete*) the joint; that he lay in bed six days, and that after that he could go about with a stick and could use the injured limb. He consequently doubted whether he had sustained a fracture at all. In three weeks from the date of the injury he was able to do light work about the house.

The following queries on the above case were put.

1. Were Surgeons H. and B. correct in diagnosing fracture of the neck of the thigh?
2. What are the effects and sequelæ of such an injury in favourable cases, and what duration of time is required for their recovery?
3. If there was no fracture of the neck of the thigh-bone, in what did the injury consist?
4. What misled the surgeons and induced them to diagnose fracture?
5. Referring to the statement of a certain G. W., who said he saw Joseph B. driving a waggon fifteen or sixteen days after he sustained the injury, should it be assumed that convalescence lasted at least twenty-six days after Joseph B. sustained the injury?
6. Was there a dislocation present? and if so, how long should such an injury incapacitate a man from following his employment?
7. In what manner was the injury caused?

Replies. 1 and 2. The surgeons were quite wrong in diagnosing fracture. The symptoms of fracture are external rotation, shortening, swelling at the hip, approximation of the trochanter to the groin, all which signs can be easily (though with pain) reduced, but reappear when the limb is let alone. Lastly, there is crepitation and absolute inability to move. Union takes two months. Now, only one of these signs—crepitation—was present, while the patient attempted to walk with a stick immediately after the injury, and fifteen or sixteen days afterwards was able to drive a waggon; and three weeks after the injury he could do light housework.

3. The swelling found by the three surgeons in the region of the hip, which involved the soft parts in the neighbourhood, indicated beyond question that the nature of the injury which Joseph B. sustained was a contusion of the joint and soft parts.

4. The fact that the diagnosis of the surgeons was determined by the presence of crepitation alone, and that they did not consider the absence of the mass of the symptoms of fracture indicates ignorance, or at least unfamiliarity with the subject. Besides, crepitation is often very difficult, and sometimes even impossible, of detection in muscles so well developed and in a man so strong as Joseph B. seems to have been.

5. After what has been said in reply to 3, it is evident that the contusion which was sustained by the patient was in and of itself a slight one, not affecting important parts, and followed by no constitutional disturbance, and that after it had for a short time seriously interfered with the movements of the right lower limb, it was remedied by the intervention of a bone-setter, without leaving any impediment behind it.

7. The contusion might have been caused by a blow, push, or fall upon a hard body, or even on hard ground.

If we reflect what are the symptoms of dislocation, it will be evident from their complete absence in this case that there was here no dislocation present.

[Would not a better and more complete explanation of this case be this? There was a contusion of the joint and a fracture of the expanded part of the innominate bone. If there were no fracture how can we account for the crepitus? Does the highly developed state of the muscles explain it? The utility of the bone-setter's treatment is easily explicable to anyone who has read the papers of Mr. Wharton Hood.—*Rep.*]

MATERIA MEDICA AND THERAPEUTICS.

BUDIN AND COYNE ON THE STATE OF THE PUPIL IN THE ANÆSTHESIA OF CHLOROFORM AND CHLORAL, AND DURING THE EFFORTS OF VOMITING.—M.M. P. Budin and P. Coyne (*Gazette Médicale de Paris*, Feb. 8, 1875) believe the observation of the pupil very useful in giving chloroform, as a guide to the state of sensibility of the patient, especially in those cases where it is important to keep the patient perfectly quiet for a long time. Experiments made upon dogs confirm their previous observations upon the human subject.

They sum up their facts thus. 'When we employ more or less powerful stimulation to subjects submitted to the action of chloroform or chloral—

'1. If there be total anæsthesia, the pupil is contracted and immovable, and remains so.

'2. If the anæsthesia be incomplete, we see the pupil dilate under the influence of the various excitements to which we submit the patient, who then struggles and sometimes groans.

'3. If vomiting supervene, we see the pupil dilate under the influence of the efforts which the phenomenon necessitates, and more or less sensibility reappears at the same time.

'There exists, therefore, a relation between the absolute insensibility of the patient and the contraction with immobility of the pupil; between the

return of sensibility and the dilatation and mobility of the pupil.'

[Admitting that the state of the pupil affords an important indication to the chloroformist, the reporter would caution against giving more chloroform without feeling that the pulse is good, since dilatation of the pupil accompanies the failure of the heart's action produced by an excessive dose.—*Rep.*]

J. T. CLOVER.

WILL ON RHAMNUS FRANGULA, A SUBSTITUTE FOR CASTOR OIL.—Dr. Ogilvie Will, assistant-surgeon to the Royal Infirmary, Aberdeen, speaks highly (*Medical Times and Gazette*, Feb. 6), of the value of the bark of this shrub as an aperient. He uses a fluid extract, of which one fluid drachm is equal to a drachm of the bark; that cut in the spring from the branches should be used, not that taken from the thick trunk. The dose is a fluid drachm for a child or half an ounce for an adult. It greatly resembles castor-oil in its effect on the bowels, acting quickly but gently, and without griping, and its taste is by no means disagreeable. J. W. LANGMORE, M.D.

OTTO ON THE TREATMENT OF EPILEPSY BY BROMIDE OF POTASSIUM.—In the *Archiv für Psychiatric*, vol. v. no. 1, is a paper by Dr. Otto on potassic bromide as a remedy against epilepsy. He employed it in thirty-one undoubted epileptics, and his conclusion, after having well-studied the experience of others and the very extensive literature already existing on the subject, is that 'it lowers the excitability of the central ganglia and of the peripheral nerves, and by this means assuages immediately the epileptic attacks.' The results are due entirely to the bromine compound. Sodid bromide acted just as the potassic salt, but potassic chloride had absolutely no action. As to the dose, the smallest for adults, to have any pretensions to result, must be 120 grains, the largest 180 grains; in some cases 225 have been borne, but when it reaches 180 grains daily the greatest precaution is necessary. It is best to begin with full doses at once, and not rise to them gradually. In more than half the cases there was complete remission of the fits, in a small number lessening of them, and not in a single instance was the remedy without some effect, whilst the psychic state was equally improved.

Of the other remedies for epilepsy, atropin has been most vaunted, and that it has an influence on the fits cannot be denied, but the influence is never more than temporary. After the remedy had been employed for months, the fits still continued under its use even increased in number and severity. Tincture of digitalis is attended with small advantages; in many cases no good results followed, in some others the attacks were diminished, but in nothing near the proportion of those treated with potassic bromide; when the digitalis was employed subcutaneously, the attacks increased to two or three times their usual number. Nitrate of silver was useless in chronic cases. Nitrite of amyl, theoretically recommended, cannot approach potassic bromide, and is very uncertain in its action even when applied as soon as an aura gives notice of an approaching fit. Some one has maintained that good results from treatment were only to be found in idiopathic epilepsy where the disease was free from alteration of tissue or pathological products. Otto's cases show, however, that such an opinion is incorrect; for, since Meynert called attention to the changes in the cornu Ammonis in the brains of epileptics,

every epileptic subject in the Pforzheim Asylum has been examined in this particular, with the result that in nearly all cases one or both of the cornua Ammonis were found to be affected, and yet in them the bromide salt had been most effectual. Under excessive doses, in some persons psychic and motor paralytic symptoms may follow, but there are symptoms of intoxication and indications for lessening of the dose, and these brain-symptoms afford just as good a guide as does the pulse in digitalis. So little fear has Dr. Otto of any permanent psychic lesion from large doses of potassic bromide, that he affirms that he has often found the intellect improve and has been able to restore to society epileptics who seemed demented. In addition to the often noticed eruption of acne in those taking this medicine, there appeared at times circular inflammations of the size of a nut, of a furunculoid character and tardy course. Occasionally (12 per cent. of Otto's cases) an extensive ulceration of the skin appeared, superficial, situated in the leg or arm, and lasting whilst the medicine was continued. In other cases there were redness of the throat, burning at the stomach, diarrhoea, and pains in the limbs, but all these were transitory, and disappeared when the dose was diminished, or when more care was taken in the mode of administration. The remedy should always be given well diluted with water.

OBSTETRICS AND GYNÆCOLOGY.

O'MALLEY ON A CYST OF SPLEEN MISTAKEN FOR OVARIAN TUMOUR.—Dr. J. P. O'Malley relates in the Proceedings of the Luzerne County Medical Society (*American Journal of Medical Sciences*) the case of Mrs. A., a native of Wales, aged twenty-five, who had been married eight years, and had had six children and two miscarriages. The last child was born in October, 1872; before its birth she thought there would be twins, as she felt two heads, and a few days after her confinement she felt a hard movable tumour about the size of an orange in her left side. It continued to grow till February, 1873, when she consulted Dr. O'Malley. He found a tumour occupying the left umbilical and lumbar regions, of oblong shape and eight inches long by four broad, and extending about two inches over the median line, with its upper border corresponding to the lower border of the ribs. It could be easily moved either upwards or downwards, but the latter movement gave the patient pain with a sense of traction. It could also be moved over to the right side of the abdomen. Moving the tumour did not move the uterus. There was dullness over the tumour, but no fluctuation; the rest of the abdomen was resonant. The urine was loaded with urates and phosphates, but contained no albumen. The patient had not menstruated for six weeks, and had morning sickness. Dr. O'Malley diagnosed either floating kidney or ovarian tumour with long pedicle. He sent her to Dr. W. L. Atlee, who would not give a positive

diagnosis, but thought it was either 'a dermoid fibroid or multilocular ovarian tumour.' He accounted for the sense of traction on downward movement by adherent omentum. The patient, after her return home, suffered from occasional uterine pains until April when she miscarried. Occasionally, both before and after her last confinement, she had suffered from convulsions; and they returned with violence in May, the fits following one another rapidly, accompanied by much pain over the tumour in the intervals. The tumour was aspirated and a quart of fluid drawn off, 'having many of the characteristics of ovarian fluid;' it collapsed, and the convulsions ceased. During the next three months she was fairly well, but had slight convulsions every fortnight, and the tumour was twice again aspirated, and, though only four or five ounces of fluid were drawn off, temporary relief was afforded. On August 12 she had chills and high fever, with great pain and tenderness over the tumour, vomiting, and tympanitis. Operation was thought of, but deferred till the violence of the symptoms should subside. On August 20 she was better, but there was still pain over the tumour, and it was rapidly increasing in size. A consultation was held and operation decided on; but another violent and similar attack on the day fixed again deferred it, and the cyst ruptured into the abdominal cavity. Operation was again fixed on, but the patient sank and it was too late.

At the *post mortem* examination four hours after death, the tumour was found to be an enlarged spleen, with a cavity in it lined with pyogenic membrane and a recent point of rupture. It was adherent to everything in contact with it. The peritoneal cavity contained a considerable quantity of pus, but there was no general peritonitis. The uterus and both ovaries were healthy.

In conclusion, Dr. O'Malley asserts that this is an unique case, for, though floating spleens have been seen, they have never been cystic. In future, the possibility of a floating spleen with cyst must be taken into account in diagnosing abdominal tumours.

[This is a very interesting case, but Dr. O'Malley is mistaken in thinking it the only one on record. Péan removed a hypertrophied and cystic spleen and cured his patient, a young lady aged twenty, in September 1867. In this case also, the disease of the spleen had been mistaken for ovarian tumour.—*Rep.*]

WOOD AND OTHERS ON REMOVAL OF THE UTERUS.—Dr. Wood, of Cincinnati, reported four cases at a meeting of the St. Louis Medical Society on October 3, 1874 (*St. Louis Medical Journal*, December, 1874).

In the first case, the tumour was a fibroid, and was removed along with the uterus. The patient lived till the sixty-fourth day, and died of phthisis pulmonalis. *Post mortem* examination showed that the operation had been quite a success.

The second case was one of multiple fibroid of the uterus, growing behind that organ, which was pushed upwards and forwards. This patient recovered so as to get up, but died of rupture of intestine (which Dr. Wood considered as an accident apart from the operation) on the twenty-seventh day.

In the third case, the tumour weighed four pounds. The patient recovered without a bad symptom.

In the fourth case, the tumour was multiple and very vascular, and weighed six pounds. The pedicle

was secured by a strong silk ligature. The patient recovered.

Dr. Wood advocates leaving the ovaries, as he thinks the patients are then in better spirits and more capable of the enjoyments of married life.

In the reports of the same society for October 10, 1874 (*ibid.*), we have a report of a fifth case of Dr. Wood's, given by Dr. Hodgen. This was a case of interstitial fibroid, and the uterus and left ovary were removed. There were no adhesions. The tumour involved the entire body of the uterus, with the Fallopian tubes springing from its lateral parts. The vessels were secured on each side by silk ligatures, as they passed to the uterus, before the pedicle was divided, it being also transfixed and tied in two halves with a strong silk ligature. Some small vessels also required separate ligature in the cut edge of the broad ligament. The ligatures had one end cut short, the others being brought out at the lower angle of the wound. The intestines were allowed to fall down into the pelvis, but the omentum was folded over them in such a way as to protect them from forming adhesions to the stump of the pedicle.

Another report of this case is given by Dr. Porter, who states that pain in the abdomen, hiccup, etc., came on after the operation, and that the treatment was full doses of calomel, colocynth, and croton oil. The patient died in forty-three hours.

Dr. Edgar also remarks on this case, and doubts whether there were any symptoms urgent enough to warrant such a dangerous operation. He also questions whether it was not a fit case for enucleation, after dilating the cervix. The treatment by drastic purges so soon after such an operation, he also calls in question, and suggests that where obstruction is feared in these cases, it might be well to try to stimulate peristalsis by electricity. He also advocates peritoneal drainage.

Dr. Wood's five cases thus show three practical successes, a result which compares favourably with the statistics of Storer, Thomas, and others.

[The separate ligaturing of the vessels supplying the uterus before dividing the pedicle, and the arrangement to avoid adhesion of intestine to stump, are both points worthy of special notice in these cases.—*Rep.*] J. KNOWSLEY THORNTON.

AVELING ON NIDATION IN THE HUMAN FEMALE. — Dr. Aveling (*Obstetrical Journal*, July, 1874), proposes to give the name of nidation to the function of periodic growth and disintegration of the mucous membrane lining the interior of the uterus, from its supposed similarity to the nesting of birds. He endeavours to show that it is a function perfectly distinct from ovulation and menstruation. The membrane grows during the intermenstrual period, attaining considerable thickness in some parts before it is thrown off (denidation.) Its microscopical anatomy has been lately investigated by Dr. John Williams, in a paper read before the Royal Society. The exact period of life when it begins to grow has not yet been accurately determined, nor also its pathology and period of greatest activity. The latter would seem to be during the week preceding the menstrual epoch, as the uterus is during that period much enlarged and swollen. There is no nidation if ovulation have never occurred, but if the ovaries have been removed after ovulation has been established, the process still continues. An ovum need not necessarily reach the cavity of the uterus ;

for in extra-uterine pregnancy the nidal decidua is formed.

Nidation is the proper preparation of the uterus for the reception of the ovum; without that, the fecund ovum cannot be matured. The exact time when the uterus is in a most fit state for impregnation remains yet to be determined, but the tenacious fluid secreted by the cervical membrane in the week preceding menstruation would, the writer thinks, be an obstacle to the passage of the spermatozoa. Dr. Aveling considers that the uterus is more particularly prepared at this time than any other for this process.

During the latter days of nidation there is often observed a sympathetic hyperæmic condition of the breasts, the latter becoming tumid, painful, and secreting a thin milky fluid. When the process of denidation is complete, all this disappears. During lactation, nidation is thought by the author to be suspended, and re-established with the cessation of that function.

Denidation is compared to parturition: the nidal membrane having arrived at maturity is thrown off at times *en masse*, but generally in more or less minute portions; with the completion of this process menstruation ceases. Menstruation and denidation being usually contemporaneous phenomena, both are believed to have separate existences. But their relative importance widely differs, nidation being essential to impregnation, menstruation not.

Disorders of Nidation.—Pain occurring in a chronically hyperæmic uterus a week or ten days before menstruation, arises, in Dr. Aveling's opinion, from nidation, caused by the increased flux of blood necessary for the formation of the nidal decidua.

Hypernidation.—When the flow of blood is very great, the nidal decidua becomes formed into a tough sac, resisting the ordinary disintegration, at least so the writer thinks. Power believed it to depend on increased ovarian action. Another theory the author suggests, viz., that hypernidation may arise from a 'missed denidation,' so that, as it were, a double nidal decidua is expelled.

Subnidation may also happen from some exhausting disease, in the same way as amenorrhœa and retarded ovulation are known to occur from like causes. An impregnated ovum falling upon an improperly prepared nidal membrane would probably be absorbed.

Abortive Nidation doubtless exists, capable of being produced by chemical, mechanical, traumatic and physiological influences, but its pathology is unknown.

Disorders of Denidation.—Difficult denidation is better known by the name of membranous dysmenorrhœa; it is, really, painful expulsion of the hypertrophied nidal decidua which prevents the menstrual flow, through obstructing the internal os and cervical cavity, requiring true uterine contractions for its removal.

Treatment.—Depletion is mostly required at the latter days of nidation, operative measures during the earlier days. Stems and tents should be inserted early in the nidal period. [Leopoldt has shown that after the decidual membrane, or, as Dr. Aveling calls it, the nidal decidua is thrown off, the lymphatic spaces of the uterus are patulous, and the ready recipients of any septic matter that may be conveyed to the uterus. Tents, as it is well known, have not unfrequently given rise to septicæmia. The reporter is inclined, therefore, for these reasons, to differ from the writer as to the desirability of introducing tents immediately after denidation.—*Rep.*]

Gravidal Nidation.—With impregnation denida-

tion is retarded; the nidal membrane grows to a considerable thickness, being only expelled after delivery, when this action is effected with uterine pains simulating those of parturition.

Dr. Aveling believes denudation from a discontinuance of the reproductive nutrition to the fully matured fœtus to be the determining cause of labour.

[Judging from the analogy of ripe fruit, this conclusion does not seem improbable.—*Rch.*]

SCHMIDT ON COMPRESSION OF THE ABDOMINAL AORTA IN POST PARTUM HÆMORRHAGE.—The following remarks by Dr. Wolfgang Schmidt (*Erztliches Intelligenzblatt*, January 12, 1875) were occasioned by a case of *post partum* flooding that happened in the author's practice, where a woman, aged thirty-two, pregnant for the third time, was attacked with flooding coupled with retention of the placenta.

She bled until she became faint and perfectly blanched. The umbilical cord had been torn through by the midwife. An attempt to remove the placenta by Credé's method was unsuccessful, and brought on an attack of faintness. The abdominal walls being very flaccid, the pulsations of the aorta were easily recognisable. It struck Dr. Schmidt to apply compression to that vessel. The effect was that the pulsations of the aorta, which were previously small and frequent, became in a few minutes gradually fuller and slower; the faintness disappeared, and consciousness returned with singing noises in the ears; after a time even this symptom ceased. As soon as the compression was removed, all the former symptoms returned. Compression was again applied with the same result, the patient complaining only of tingling and numbness of the lower extremities, showing how effectual had been the pressure. The patient made a good recovery. Some authors placed compression and transfusion alongside of each other, and as Herr Schmidt thinks, properly so; as, although general increase in the quantity of the blood is not attained, yet in the vital organs such is obtained, in the foremost rank of which stands the brain. Besides, transfusion is not capable of easy or rapid application, and assistance, both instrumental and manual, is requisite; a not unimportant factor in country practice.

W. C. GRIGG, M.D.

OPHTHALMOLOGY AND OTOLOGY.

SCHNABEL ON THE DEVELOPMENT OF SHORT-SIGHT IN CONSEQUENCE OF OVERWORK OF THE EYES.—This paper, on the influence of fatigue of the ciliary muscles upon the development of myopia, was communicated to the Medical Society of Vienna (*Allgemeine Wiener Medizinische Zeitung*, October 27, 1874). It appears that there are at present two opposing theories as regards the formation of staphyloma posticum; the one holds that a congenital predisposition is essential to its development, and the other maintains that overwork on the part of the ciliary muscle is sufficient to produce it in any and in every kind of eye. The advocates of the latter theory assert that, in consequence of prolonged hard work, the ciliary muscle is seized with cramp and remains in a state of spasm; that hyperæmia and inflammation of the choroid are the result; and that these in

their turn lead to the atrophy of some portion of the optic disc, and to the formation of the well-known myopic crescent which precedes the elongation of the eyeballs. Dr. Schnabel considers this explanation to be in the highest degree improbable; for, instead of spasm being the outcome of fatigue of the ciliary muscles, he would expect a relaxation; and he asks why this state of spasmodic cramp should occur frequently in cases of myopia when the need of the accommodation is but lightly felt, rather than in hypermetropia in which the demands upon the accommodation are excessive and persistent. He adds that, amongst 210 cases of hypermetropia, he had not been able to find a single instance in which this spasm had occurred, a fact which convinces him that any such cramp or spasm cannot be the cause of the elongation of the eyeball. He allows that, amongst 105 eyes, Dobrowolski found sixty-nine in which there was spasm; that out of sixty-seven eyes, Hosch found forty-six so affected; and amongst 101 eyes, Schiess found fifty-one in which the myopia entirely or in part depended upon the cramp of the accommodation; but he believes that all of these observers have forgotten that a single instillation of atropine is sufficient to relax the accommodation and at the same time to diminish the refraction in any kind of eye; and that a prolonged rest of the ciliary muscle is always attended with a marked diminution in the refractive power; that hypermetropes do not suffer from this kind of cramp; and that, while occasionally the refraction appears to be higher than it really is, owing to some anomaly in the accommodative power, yet this is not sufficient to prove the existence of a distinct muscular spasm.

The existence of a crescent most certainly cannot be said to be due to the struggles of the ciliary muscle in a state of cramp, because most perfectly formed crescents may be seen in eyes in which the accommodation has never been in the least degree strained; neither can a myopic crescent owe its existence to a painful exercise of the accommodation, for under such circumstances it should be circular, and not, as it is, semilunar in shape; it should be deeper on the inner than on the outer side, and should have its narrowest diameter on the outer side, whereas, as everybody knows, the reverse is generally the case in all these particulars; and it should occur, as a rule, in hypermetropic eyes, and as the exception in eyes which are myopic.

In conclusion, Dr. Schnabel considers that there are two kinds of crescents. One is congenital and entirely unconnected with staphyloma posticum; it may be met with in eyes presenting every variety of refraction, and may be looked upon as the analogue of choroidal coloboma; in this variety, the nerve-fibre layer of the retina and the pigment-layer of the choroid are more or less deficient. The other is due to staphyloma posticum, in which the retina and the pigment-layer of choroidal epithelium become atrophied. Both the congenital crescent, as well as the acquired crescent, may involve the region of the yellow spot.

The Breath, and the Diseases which give it a Fetid Odour; with Directions for Treatment. By JOSEPH W. HOME, M.D. Appleton & Co., New York. 1874.

In the preface to this handbook the author states : 'Marked changes in the breath have heretofore received little consideration from the profession. Our medical text-books contain scarcely an allusion to their existence. It is to supply this want in medical literature that the present book has been published.' If Dr. Home has really written for the medical profession, we doubt the want which he presumes his book will supply.

Most surgeons and physicians are acquainted with the characteristic odour of the breath that is found associated with mercurial salivation, syphilis, and phosphorus-necrosis, whilst the effect of diseased teeth as a cause of offensive breath has not hitherto been overlooked. We presume, however, that Dr. Home has not written for his professional brethren, but for the public, since he deems it necessary in the text to explain matters with which all competent physicians are fully acquainted. For the public, also, he has written (if they read the book) too much for their peace of mind to remain, and too little for them to receive any reliable instruction.

As most people at some part of their lives are likely to suffer either from excessive emotion, constipation, or indigestion, and all these conditions produce fetor of the breath, according to Dr. Home, we find instructions given for constitutional treatment by the patient himself (or herself as the case may be); whilst, in the absence of a dentist, they may dissolve the accumulations of tartar off the teeth by means of dilute acid. On the condition of the breath in health and disease, Dr. Home might have written a treatise of signal use to the public; but he has, in our opinion, only produced a work that will be likely to mislead those for whom it is clearly intended.

OAKLEY COLES.

MISCELLANY.

PROFESSORS RIZZOLI and Scarenzio and Dr. Ciniselli, have been nominated corresponding members of the Lombardian Institute of Science and Literature.

THE *Gazzetta delle Cliniche* announces the recent death of Dr. Carlo Burci, professor of Clinical Surgery in Florence, and senator of the kingdom of Italy.

CAUSES OF EXEMPTION FROM MILITARY SERVICE IN FRANCE.—The report lately distributed to the French Deputies gives some interesting particulars on the manner in which the new law on compulsory military service is working. It appears that 303,510 young men figured on the list, of which 30,433 were excused on the ground that they were suffering from diseases which rendered them unfit for service. The list of these diseases is curious from a physiological point of view. They are classed as follows:—Skin-diseases, 795; blindness, 120; loss of an eye, 1,325; squinting, 125; short sight, 527; various diseases of the eye, 1,879; deafness, 691; loss of teeth, 315; stuttering, 529; wens, 416; scrofula, 1,336; heart-disease, 735; consumption, 522; hernia, 1,942; loss of the use of an arm or leg, 1,883; mutilation of fingers, 1,038; varicose veins, 818.

PHOSPHORUS DISEASE.—In Mr. Salter's recently published work on *Dental Pathology and Surgery*, he devotes a chapter to phosphorus disease, a subject upon which he speaks with some authority. He alludes to the preventive measures which ought to be adopted. 'The prevention of phosphorus disease is so easily accomplished, that its occurrence is discreditable to the sanitary laws of any country where it occurs. If the employment of amorphous phosphorus were decreed, and the use of ordinary phosphorus prohibited by statute, the disease, in all probability, would cease to exist. But if this could not be enforced, the employment of ordinary phosphorus might be rendered almost innocuous.' Amongst other precautionary measures, he enjoins 'a periodic and rigid scrutiny of the mouths of all the workpeople employed.'

VACCINATION IN ROME.—Last month, the provincial Sanitary Council of Rome, finding that animal vaccination in Rome and in the entire province was unsuccessful, unanimously urged the Minister of the Interior to nominate one of its members as provisional conservator of vaccine for the commune of Rome. The minister, recognising the importance of the subject and the urgency for making some provision, seeing that the province was threatened with an epidemic of small-pox, has given notice to the Prefect of Rome that, in the official vaccinations in the province, animal lymph is to be abandoned, and humanised lymph used, as was formerly done. The *Gazzetta delle Cliniche*, while approving of this order, points out that it is also necessary to provide a system of preservation and cultivation of vaccine lymph, so as to insure a constant supply for the province under all circumstances.

DARK ROOMS MADE LIGHT.—Chappuis' Patent Reflectors are used to reflect the daylight, and do away with gas during the day time, thus saving expense and ministering to both health and comfort. They can be adapted wherever there is either window, skylight, fanlight, area, grating, or any communication with the outward daylight. These reflectors are made of crystal surfaces, corrugated or shaped according to scientific principles, and coated with deposits of pure silver, also of silver-plated metal, rendered water and air-tight and fitted in well-constructed frames of different shapes and sizes as required. Being fixed outside windows or under skylights, they reflect the daylight rays and diffuse them in all places or apartments where the natural light is insufficient, owing to the small size of windows or the proximity of walls, houses, etc. Mr. Chappuis' patents are patronised by H. M. Commissioners of Works, the Royal Engineers, the Admiralty, all leading architects, contractors, bankers, merchants, manufacturers, etc.; they are also in general use for private houses, institutions, etc., upwards of twenty thousand having been supplied since 1831. The reflectors may be seen in operation and prospectuses obtained at the manufactory, No. 69 Fleet Street.—[Adv't.]

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON CATARRH OF THE SMALL INTESTINE IN CHILDREN. BY DR. ALOIS MONTI, OF VIENNA.*

(Continued from page 115.)

Chronic catarrh of the small intestine is either developed from the acute form, or the catarrh assumes a slow course from the commencement. In this form, the stools are not so profuse and frequent as has been described at p. 115; from five to eight stools take place within twenty-four hours. Defecation is always preceded by colicky pains, and is attended with groaning and whining, or with rumbling of the bowels; the stool is principally watery, and contains a yellow crumbly mixture. Its consistence is thin or pappy; its colour yellow, yellow-green, or whitish. It also contains remains of undigested food. In spite of the diarrhoea, the meteorism continues; it usually increases during digestion, and sometimes colicky pains set in, but are not followed by faecal evacuations. The appetite is in many cases undisturbed; in others it is either diminished or quite lost.

The duration of chronic intestinal catarrh is very variable; it may last from four to six weeks, or even two or three months or more. The symptoms seldom remain of equal intensity through the whole course of the disease; sometimes improvement appears, or even recovery, for a few days, but after a short time, without apparent cause, a relapse occurs; and thus the patient's condition often changes several times in the course of the illness. Chronic catarrh of the small intestine exercises a very injurious influence on the nutrition of the child; usually, at the commencement of the illness, there is a standstill, while later on emaciation appears, and may reach the highest degree. In children thus affected, I have met with all degrees of emaciation, from slight diminution of the panniculus adiposus to complete atrophy of the muscles, as seen in the well-known miserable creatures with aged face, hollow cheeks, sunken eyes, and dry wrinkled skin. As soon as general nutrition becomes injured by chronic catarrh of the small intestine, the growth of the bones is generally arrested, and the phenomena of rachitis are developed, and reach a degree of intensity proportionate to the duration of the disease.

Recovery from chronic intestinal catarrh was observed in three cases in which the disturbance of nutrition had not reached the highest degree. But where the muscular structure was altogether wasted, and where the skin presented a dry appearance,

hæmorrhagic effusions, or œdematous swellings, recovery was very rare.

A frequent result of chronic intestinal catarrh is atrophy of the intestine.

The chronic form of catarrh of the small intestine was chiefly observed in children under one year, and in those which had been artificially fed.

Children affected with chronic intestinal catarrh frequently die of intercurrent complications.

Complications.—Among the complications met with, the following deserve notice.

1. *Dyspepsia.*—This complication was principally observed in children at the breast, in whom the intestinal catarrh was induced by too frequent and excessive feeding. It either preceded the development of the intestinal catarrh by a few days, or appeared at a later period in the course of the disease. In both cases, the symptoms of dyspepsia accompanied those of intestinal catarrh. In such cases, the presence of dyspepsia indicated a somewhat protracted illness, and the repeated violent attacks of colic were often very distressing and painful to the little patients.

2. *Gastric catarrh* occurred as a complication in eleven cases. One was a child four months old, artificially fed; the remaining ten were between one and two years old. I have observed this complication principally in those cases in which the intestinal catarrh was produced by error in diet, or by deficient food not suited to the child's age. As with dyspepsia, gastric catarrh sometimes preceded the intestinal catarrh; but in most cases the two appeared simultaneously. I have seen this complication only in acute cases of intestinal catarrh; in some cases the simultaneous occurrence of the stomach-disease produced rapid collapse, the patients presenting a choleraic appearance. The course of the complication was mostly of short duration, and ended in recovery.

3. *Diseases of the mouth* frequently occurred in the course of intestinal catarrh. In six cases there was thrush; in three, aphthous stomatitis; and in three, desquamation of the tongue. The thrush occurred only in the acute cases, while the aphthous stomatitis and desquamation of the tongue accompanied the chronic form of the disease. In two cases there was secondary diphtheritis of the mucous membrane of the lips.

4. *Œdema of the meninges* occurred in one case of chronic intestinal catarrh, and ended fatally.

5. *Bronchial catarrh* was observed as a complication in eleven cases, six of the acute form and five of the chronic. In two cases of chronic intestinal catarrh, the complication appeared in the form of acute capillary bronchitis, and ended in death. In the remaining nine cases, it occurred as a chronic bronchial catarrh.

6. *Lobular pneumonia* appeared in one case of chronic intestinal catarrh, in a child sixteen months old, and caused death.

7. *Indications of a high degree of scrofula* were observed in four cases of chronic intestinal catarrh.

8. *Eczema* was observed as a complication in nine cases, all of chronic intestinal catarrh.

9. *Prurigo and ecthyma* were each observed in one case.

10. *Cachectic pemphigus* occurred in the course of chronic intestinal catarrh in two children, aged four and eight weeks. Both died.

11. *Gangrene of the skin* appeared in one case of chronic intestinal catarrh in a child three months old, which had been artificially fed in a highly im-

* From the author's 'Pædiatric Contributions,' about to be published. *Wiener Medizinische Wochenschrift*, nos. 1 et seq., 1875.

proper manner, and in other respects badly managed. The intestinal catarrh had lasted eight weeks, and had produced extreme emaciation. Behind the right ear, the skin over the mastoid process and in the immediate neighbourhood was infiltrated and of a purple colour. The next day, the skin at this part was converted into a gangrenous eschar, which showed no limitation on any side. In spite of treatment, the gangrene spread over the temporal region and caused death.

In the material of a polyclinic, it is not possible to collect certain data as to the mortality caused by intestinal catarrh, as, notwithstanding all care in following up the cases, we cannot arrive at the knowledge of every death that occurs. I must, therefore, abstain from deriving any statistical results from my observations on this subject, and will only point out a few general facts regarding the mortality from this disease.

In the first place, the age of the child must be taken into consideration, for the younger it is, the more readily may an attack of acute or chronic intestinal catarrh end fatally. Further, the diet of the child is of great importance; when it is fed with human milk, the mortality is very small, while in artificially fed children it attains frightful dimensions. Finally, the complications of catarrh of the small intestine are, according to their nature, to be regarded as the proximate cause of death.

The *Treatment* of catarrh of the small intestine was, according to the nature of the case, dietetic and causal. Medicines were only given to meet symptoms, and with the object of assisting the action of the dietetic treatment. In each case of intestinal catarrh I have directed my whole care to the regulation of the diet, and I have to thank alone the rigorous and intelligent carrying out of this fundamental principle for many successful results. In the regulation of diet, I have especially borne in view the following points.

In the case of children at the breast suffering from internal catarrh attributable to too frequent or immoderate suckling, a rigorous order as to giving the breast was enforced. When a bad condition of the milk of the mother or nurse could be regarded as the cause of the disease, a change of nurse was tried. Unfortunately, through the poverty of the patients attending the polyclinic, this was impossible in most cases, and I was obliged to have recourse to substitutes for human milk, and to use them either exclusively or as a supplement to the breast. In this respect Liebig's soup, and Löflund's and Nestlé's children's food, have done good service in many cases of catarrh of the small intestine. When artificial food had been given along with the breast-milk, and intestinal catarrh had become developed in consequence, the food in question was withheld during the disease.

When intestinal catarrh appears after weaning, it is necessary to return to the breast-milk in cases where the symptoms of the disease come on impetuously, or where they have continued some time and no improvement is manifest, notwithstanding dietetic and medicinal treatment, especially in children under five months old and in summer time. If circumstances do not allow the child to be put to the breast, I try the best substitutes, such as veal broth with milk, Liebig's, Löflund's, or Nestlé's food, good fresh cow's milk, which may be given either pure or diluted, according to the age of the child, or finally, dencondensed milk. With these substitutes I have the children fed, and I have found it advantageous to

give fluid food alone and to avoid amylaceous diet. The entire withdrawal of milk after weaning may be tried for a single day; for a longer time, according to my experience, it is hurtful.

In artificially fed children under one year of age, the substitution of natural nourishment by breast-milk is the most efficient means of curing both acute and chronic intestinal catarrh. Here, also, as I have said elsewhere in speaking of dyspepsia, too many experiments should not be made with artificial food, and nourishment with breast-milk must be used when there is no improvement in the intestinal catarrh in spite of the use of the best substitutes for human milk, or when the nutrition is essentially interfered with. In the cases of the polyclinic, on account of their indigence, this object could be carried out in a few only.

In regulating the diet, I generally followed the principle of changing the food during the use of which the intestinal catarrh had set in, and replacing it by another which produces the least irritant effect on the intestinal canal, and approaches nearest to breast-milk in digestibility. In cases of intestinal catarrh in artificially fed children, many hold to the opinion that feeding with milk should be entirely stopped if the disease commenced under its use. Vogel alleges that no child with intestinal catarrh tolerates cow's milk, and therefore he recommends that mucilaginous drinks and soups be substituted for it. Quite recently, also, Demme has defended this opinion of Vogel, and asserts that the administration of milk in intestinal catarrh is to be rejected as improper. The latter, however, rejects not only fresh milk, but also condensed milk, as well as Liebig's soup and Nestlé's children's food; and advises that children suffering from intestinal catarrh be fed only with meat-broth or albumin-water. This is not the place to prove that assertions of this kind are perhaps based on insufficient experience; and I will merely remark, that in twelve years Demme has treated only seventy-one cases of intestinal catarrh. My experience of many years, in the children's hospital, as well as in the polyclinic and in private practice, does not confirm the assertion referred to above. In children above one year old, very good results may certainly be obtained by withholding milk for some days; but in infants under three months, I regard abstinence from milk as extremely injurious, and as the most frequent cause of rapid collapse and death.

It may be not without interest to remark here, that Demme mentions twenty-two fatal cases of intestinal catarrh in children of ages varying from a few weeks to two years, and that seventeen of the deaths took place in children of or under ten weeks old. This, perhaps, indirectly confirms the correctness of my assertion. It is especially to be regretted that Demme, in his yearly report, does not give any table of the ages of his cases of intestinal catarrh, from which the percentage of mortality might be calculated; for only with the help of such a table would it be possible to prove his opinion. The want of it is all the more to be lamented, as there is some reason for believing that most of the children died who, within the above-mentioned age, were treated by the total withdrawal of milk.

I have only brought forward these remarks, for the purpose of in some way explaining how it is that my experience stands in glaring contradiction to that of Vogel and Demme.

(To be continued.)

VANZETTI AND VERNEUIL ON THE ARREST OF HÆMORRHAGE FROM WOUNDS.

In a paper read before the Royal Venetian Institute of Science, Literature, and Art, and since published as a separate pamphlet,* Professor Vanzetti treats of the arrest of hæmorrhage. He signifies by the word 'uncipressione,' pressure made on a vessel, or vessels, laid open in a wound, by means of two sharp hooks plunged deeply into each side of the wound, and held asunder by means of a ligature attached to their handles and fixed either to a splint on which the wounded part rests, or otherwise, so that the lips of the wound may be kept dilated, and the bleeding vessel pressed upon by the tension of the hooks. He commences by calling attention to the great difficulty which is sometimes experienced in arresting hæmorrhage, in situations where (as in the palm of the hand) it is difficult to tie the wounded artery at once, and to the frequency with which in such cases consecutive aneurism occurs. He then goes on to speak of his new proposal as 'a surgical proceeding, so simple, so obvious, so easy, so natural, so common, I had almost said so vulgar, that I should doubt whether this were the place to speak seriously and formally about it, were it not that its effect may be sometimes decisive as to the life or death of the patient. It offers itself so spontaneously almost to the mind, even when an artery is to be tied, as to cause astonishment that it has not, so far as I know, been treated of by any one as yet with the deliberate end of using it to check hæmorrhage. To put it in practice, it is not necessary to attempt to bring the artery into view (for, if this can be done, it ought to be tied): no scalpels are wanted to make new incisions, no forceps, no tenacula, no ligatures, no bandages, no compresses, no plugs, no new instruments or inventions; and every surgeon, even the least experienced, called on however suddenly and unaided, can provide himself in a moment with what is wanted, whether in the mansion of the rich man, in the garret of the pauper, or in the hut of the peasant.'

The author goes on to relate three cases. The first was one of a deep wound in the palm of the hand, between the first and second metacarpal bones, treated by compression, with recurrent attacks of hæmorrhage during twenty-eight days, when the patient was brought to the hospital in a desperate state of anæmia. The wound was dilated, and an attempt made to find the bleeding vessel. This, however, was not very satisfactorily done. Two ligatures were placed on points from which the hæmorrhage seemed to issue, and for the time the bleeding was checked. Then the wound was kept dilated with double sharp hooks, fixed to the splint on which the hand rested. No further bleeding occurred till the second day, when it broke out in a large stream. The bleeding vessel could not be found, but the hæmorrhage ceased on fixing deeper and more securely one of the hooks which had become displaced. Again, on the same day, the bleeding recurred from the other side of the wound, and was again controlled by refixing the opposite hook. After this, no further hæmorrhage took place. The hooks were removed forty-eight hours after the last application, and all went well.

This case seemed to show that the bleeding had been checked, not by the ligatures, but by the hooks, which must have enclosed in their curve and compressed the two bleeding ends of the artery; still the fact that ligatures had been applied renders the case not perfectly convincing, and it might even have been argued (though this is highly improbable) that the bleeding ceased spontaneously on the mere enlargement of the wound.

The second case was that of a lad who, in cutting a piece of cheese, wounded his hand about the centre of the palm. He ran to the hospital, bleeding violently. On undoing the wrappings from his hand, it was seen that the wound was transverse, lying between the second and third metacarpal bones, only about two-fifths of an inch (one centimètre) in length and about the same in depth, and bleeding furiously whenever the brachial artery was not compressed. The hand was laid on an inclined plane, and two single sharp hooks were fixed deeply into it. The bleeding ceased, almost before the pair were fixed; in fact, it seemed as if traction on one of them arrested it. Next morning, the boy, not understanding why his hand should be hooked down in that way, gently withdrew the hooks, and no further bleeding took place.

The third case was that of a cabinet-maker, who had wounded the ulnar artery about two inches above the wrist, with a sharp knife. He had lost a large quantity of blood, and fainted frequently, before he was brought to the hospital. There the house-surgeon tried to find the wounded artery, but without success, and seems not to have enlarged the wound. However he repressed the hæmorrhage for a time by pad and bandage; but, just as Professor Vanzetti was visiting him next day, the bleeding recurred very copiously. The bandage was undone; a perfectly transverse wound, about half an inch long was seen, from which the blood burst out whenever compression of the brachial was intermitted. Professor Vanzetti thus describes the treatment. 'I at once insinuated two single hooks into the wound, and separated its edges in a very oblique direction, for the purpose of better embracing both ends of the wounded artery; but the attempt quite failed, so did a second which I made with the hooks drawn in a different direction, and with more force; so did a third, and, during the three intermissions of the pressure, a lake of blood had collected around the arm. I cannot say how much I felt my confidence in the hooks fail at these repeated failures, and how depressed and uneasy I felt—but it was only for an instant, for a double hook substituted for the single one at the upper edge of the wound stopped the bleeding at once, and permanently.' The hooks were secured to pieces of wood fixed on the sides of the bed. The upper hook could be seen pulsating with the movement of the artery which it embraced, and this pulsation was perceptible for about a day. The hooks were removed in forty-eight hours.

The paper concludes with minute directions for all the details of 'uncipression'; viz., the time of maintaining it—twenty-four, thirty, forty hours or more, according to the severity of the bleeding; the form of hooks, whether single or double, in a handle, or secured with a chain or elastic cord, like dissecting hooks; the direction of pressure; the mode of providing the fixed point for the hooks, as by splints; the bedstead, pieces of furniture beside the bed, etc. All this the surgeon can, however, easily contrive for himself. Finally, Professor Vanzetti suggests

* *Della Uncipressione*. Memoria del Prof. T. Vanzetti. Venezia, 1874.

that in lieu of the hooks some expanding instrument (similar, as he says, to the speculum oculi) could be used to keep the wound expanded and compressed by excentric pressure.

In reference to Professor Vanzetti's paper, M. Verneuil read to the Société de Chirurgie (*Gazette des Hôpitaux*, January 9, 1875), a memoir entitled on 'Forcipation,' giving examples of another mode of stopping hæmorrhage, of which, as he truly says, he is not the inventor, but which, he thinks, is not so much known as it should be. It consists merely in seizing the bleeding point with a pair of forceps, which are closed either by a spring of their own, or by a ligature tied round their blades, and left in the wound. [Probably few of our readers who have had much experience of operative surgery have not seen something of this kind either done or attempted with varying success.] M. Verneuil gives twelve examples of this practice in cases of very various kinds. He has generally used either a pair of forceps, similar to those called 'torsion-forceps' in this country, or a common pair of dressing-forceps. In all the instances here given, the bleeding was permanently commanded. They were (1) a case of section of the pedicle of an uterine polypus; (2) a wound of an artery in the palm; (3) a wound of the internal mammary artery in removing carious bone from the sternum; (4) a wound of the internal maxillary artery, in removing a tumour of the jaw; (5) a wound of the lateral sacral artery in operating on a case of caries of the sacrum; (6) bleeding from the base of a nasopharyngeal polypus; (7) a second case of wound of the palm, in which four pairs of forceps were left in the wound for six days, when they fell away spontaneously; (8) an amputation of the thigh in the country, where, however, the forceps were only used temporarily during the operation, for want of a skilled assistant; (9) a wound of an artery in the removal of a tonsil—the patient, a student, having operated on himself; (10) bleeding from the diploë in trephining, where M. Verneuil compressed and crushed the bone in a pair of pincers; (11) bleeding from an artery, laid open in making incisions in diffuse inflammation, which could not be tied from its having retracted; and (12) an operation for the extirpation of an aneurism by anastomosis, in which a circle of thirteen pairs of forceps were left on for six or seven days, when they came away of themselves. [It is obvious that in some of these instances acupressure could have been used, and probably with more advantage, while in others most English surgeons would have resorted to the cautery, or to torsion; but where the vessel wounded is in a deep and narrow cavity, the method, though no doubt a rough one, is probably superior to any other form of compression, even when any other could be employed.—*Rep.*] T. HOLMES.

WARLOMONT ON THE CASE OF LOUISE LATEAU, THE MYSTIC OF BOIS D'HAINES.

An extraordinary meeting of the Royal Academy of Belgium was summoned for February 13, to hear the report of the commission appointed to report on a memoir by M. Charbonnier on 'The Disease of the Mystic, Louise Lateau.'*

M. Warlomont, the reporter appointed by the commission, said that it was originally appointed to

read and report on M. Charbonnier's work, but that the members of the commission felt that such a proceeding would be very inconclusive without actual medical observation of the facts which it related; they therefore proceeded to the spot, and made the investigations detailed in the following report.

Dr. Warlomont acknowledges that no obstacles were placed in his way; on the contrary, every facility was given for his investigations, so long as they were confined to the phenomena which could be observed by day. What takes place by night is, as yet, unknown to the commission, as well as to all the rest of the world, and herein lies the great hiatus.

Louise Lateau was born at Bois d'Haine, in Belgium, where she still lives, on January 30, 1850. She had a miserable childhood, troubled by numerous diseases; the menses only appeared when she was eighteen years old. In March, 1868, she felt wandering pains of great intensity, completely lost her appetite, and brought up blood on several occasions. She passed a whole month on low diet, and consequently fell into a state of such weakness, that on April 15 the last sacraments were administered to her. However, she soon rallied. On the 19th, the periodic function commenced, and lasted three days, when she grew better so rapidly, that on the 21st she was able to go to mass in the parish church, about a mile and a quarter distant from her home. With regard to her mental condition, Louise had always liked solitude and silence; from her earliest childhood she repeated her morning and evening prayers with the utmost fervour, and had a particular love for prayers relating to the passion of the Saviour. When quite young, she often performed the devotions known as the stations of the cross, and told her beads every day. She made her first communion in 1861, and from that time took the sacrament first every fortnight, later on every Sunday, and after Whitsuntide of 1868 every morning. Such was the mental and physical condition of Louise Lateau at the time when the more special manifestations, the ecstasies and the stigmata, which have so strongly attracted public attention, both by their symptoms and their periodical return on the Friday of each week, began to display themselves. The commission confine themselves only to recalling this event, which however is not strictly authenticated. From this time they only relate facts which have come under their own observation.

In order to make his medical observation, M. Warlomont visited Louise Lateau three times on Friday, four times besides on the days on which the paroxysms occurred, and submitted her to long and minute examinations. In addition to the ecstasies and stigmata, the girl also presented another very extraordinary phenomenon; she was asserted not to have taken any food or drink since March 30, 1871. This allegation has given a particular direction to some parts of the medical inquiry. However it may be, the principal features of this inquiry are as follows: Height, one mètre sixty-three centimètres (5 feet 4.2 inches); weight, fifty-three kilogrammes (8 stone 4.7 lbs.); greenish-yellow complexion: conjunctiva, gums, soft palate and external ears colourless; skin dry, marking twenty-five kilogrammes by Regnier's dynamometer; pulsation of the heart feeble, without intermission; respiratory sounds soft in the first instance, equally perceptible at the level of the aorta and the carotids; arterial pulsations regular, varying from

* This report is given in the *Gazette Hebdomadaire*, February 19, 1875.

80 to 130, according to the period of examination; lips red; teeth white and good; the soft palate and uvula of the pharynx were sensitive to the touch, which however did not produce any reflex movement. Louise Lateau herself stated that she had not had any action of the bowels for three years and a-half. The respiration was normal, and the gases expired contained in perceptibly normal proportions the vapour of water and carbonic acid. Louise declared that she was constantly in pain all over her body, but that these pains were specially concentrated in the regions where the stigmata appeared, the backs and palms of the feet and hands, the left side, and the right shoulder; and that they became particularly intense on Fridays. The epigastric and dorsal pains peculiar to hysterical subjects were entirely absent. She said that since she had ceased to eat and drink, she no longer passed urine. Menstruation had remained regular. The blood, examined by the microscope, was normal as to its anatomical elements, but serous, and contained a large relative proportion of white corpuscles. Special scenes took place every Friday, which were in preparation on the Thursday. On that day Louise was up and going about as usual, but suffering from headache, hot and dry skin, full and quick pulse; in one word all the signs of a violent *molimen hæmorrhagicum* were present to a large extent. From eight o'clock on Thursday evening until nearly six o'clock on Friday morning she remained alone in her cell, without a bed on which to lie down; she affirmed that she watched and prayed. No one, however, has witnessed her proceedings. When M. Warlomont, entered her room about six o'clock one Friday morning, he found Louise seated on the edge of a wooden chair supported by the wall opposite the window, and consequently in full light. The upper part of her body was slightly leaning forward; her hands were clasped under a white linen cloth spotted with freshly shed blood. Her huddled-up attitude was that of great suffering. Dried blood was visible on her forehead. Her cheek-bones were red, and she was in full possession of her senses.

On Fridays, blood flowed from different parts of her body. The following are the particulars on this point observed by M. Warlomont on his first visit on September 18, 1874. The upper part of the forehead was covered with dried blood which, it appeared, had flowed from midnight until six o'clock in the morning, but had then stopped. When washed with a wet towel, the forehead became perfectly clean and remained in the same condition the rest of the day. The epidermis, when examined with the magnifying glass, showed neither erosions nor scratches. In the backs and palms of both hands there were two bleeding wounds, from three-quarters of an inch to one inch long, wider in the centre than at the ends. Red blood, like the blood of the capillaries, flowed incessantly drop by drop, and almost continuously from these four wounds. The stigmata of the back of the hand were in the centre of two shining nodes, hard to the touch and painful. Examined by the magnifying glass, the depth of the wound showed red, turgescient, acuminate papillæ of the dermis, in some places resembling true proud flesh. A fragment of the dorsal stigmata of one of the hands, taken out by the scissors, showed under the microscope a papilla of the dermis and some capillaries considerably increased in size. The wounds of the two feet resembled those of the two hands, but were of smaller extent. They had only yielded a little blood. Louise had kept on woollen stockings, which

had probably contributed to arrest the flow. The bleeding on the left side followed the level of the space separating the fifth from the sixth rib, outside and a little below the centre of the left breast. The wound was about half an inch in diameter, and had yielded but little blood. There was a wound of about an inch and a quarter square, which strongly resembled the epidermal surface denuded by an ammoniacal blister. The wound was open, and large drops of serous matter, and some small drops of blood, exuded from it. It appeared that, at the outset, the hæmorrhage was always preceded by the formation of blisters, but those were no longer produced. It was also said that at first the wounds became cicatrised the day after their appearance; but such is not the case at present; the dorsal wounds of the hand having no longer the time to close up completely between one paroxysm and the next. At a quarter past six o'clock, the communion was taken to the penitent in her own cell. She knelt down, received the host, and then remained for half an hour in a state of ecstasy, during which, she appeared insensible to all outward distractions. At the end of half an hour she again seated herself on her chair, and resumed her former attitude, in which she remained until a quarter past two. At this time she fell into a fresh ecstasy, and those desirous of witnessing the sight were introduced, to the number of twenty-five persons, into a cell capable of containing ten with comfort. The ecstasy comprised three stages or periods. In the first stage Louise was seated on her chair, her body bending forwards; her eyes were wide open, fixed, turned upwards, and to the right. The pupils were dilated, and light did not at first cause contraction. Sight appeared annihilated; nevertheless, there was a slight winking of the eyes when the finger was sharply applied to them. She was insensible to all irritations, prickings, and pinchings; the strongest electric current did not provoke any reflex movement. The hearing was closed to ordinary excitements. The region of the stigmata, painful up to that time, could be pressed, pinched and rubbed vigorously, without causing any manifestation of pain. In the second stage, the girl fell on her knees, remained about a quarter of an hour in that attitude, then returned to her seat. The third stage was that of prostration; towards three o'clock she bent a little forward, rose slowly, then laid herself down, with her face on the ground, without rigidity or haste, her two knees first touching the stone floor, then her elbows and face. Her arms were extended in the shape of a cross, her feet joined together. During this stage, which lasted an hour and half, her circulation and respiration underwent various changes, too long to detail in this report. She rose from this position about half past four, and immediately recovered consciousness. Her pains, until then unfelt, returned, and gradually diminished, until they disappeared at half-past eight, when the paroxysm finished, to be reproduced on the following week.

The commission appointed by the Royal Academy of Belgium to investigate the case of Louise Lateau have reported that the genuineness of the ecstasies is uncontestable. As to the stigmata, of which the spontaneity of their production was strongly questioned, the commission not being able to arrive at the primary cause, whether mechanical or spontaneous, which gives rise to them, it was necessary for them to confine themselves to making certain of the manner, whether spontaneous or artificial, by which

the hæmorrhages are produced. In order to determine this point, it was necessary to resolve the following problem : to place one of the stigmatised hands, before the bleeding, on the evening before the crisis, in an apparatus which, without altering any of the physiological conditions of the part, would render impossible the contact of any penetrating instrument or the intervention of any process capable of making it bleed ; and to keep on this apparatus from the Thursday to the next day. For this purpose M. Warlomont invented a very simple apparatus, which realised the desired conditions ; it consisted of a glass globe about four inches in diameter, having a neck like an ordinary bottle at one of its poles, and at the other pole another neck about three inches in diameter. The first neck was closed by a cork, traversed by a bent glass tube not extending beyond the outside surface of the cork. The inside end of the cork, as well as that of the tube, was covered by a wire gauze, not interfering with the ingress of air, but preventing the introduction of any penetrating instrument. The corks and tubes were fixed by several seals. The second neck was covered with a kind of muff or sleeve of India-rubber cloth, fixed to its outer rim by India-rubber cement and sealed with six seals. This apparatus was put on by M. Warlomont and Dr. Duwez on Thursday, January 21, at 2 P.M. After the absence of any flux from the stigmata had been verified, the patient's right hand was introduced into the bottle through the large opening, then the kind of muff or sleeve was brought down over the arm, which it covered as far up as the sleeve of the chemise ; it was cemented to the arm by the same adhesive application, then finally closed up by a bandage, nearly an inch wide, brought twice round the arm, and carefully sealed up. This done, all the apparatus was enveloped in a bag of gutta-percha cloth, fixed to the shoulder by two turns of another bandage, sealed with two seals. The India-rubber and gutta-percha cloths would inevitably betray the passage of the finest needle. On Friday, the 22nd, at half-past ten o'clock in the morning, M. Warlomont entered Louise Lateau's cell, accompanied by Professor Crocq, of Brussels, who had undertaken to remove the apparatus and declare the result. It was this : 'The right hand was closed up in the apparatus which M. Warlomont had fixed on the previous evening. The apparatus was perfectly intact, as we assured ourselves by the most careful examination of the outer envelopes and the seals, not one of which bore the slightest trace of having been tampered with. The sloping portion of the receiver was filled with a small pool of liquid blood, and the back and palm of the hand were covered with clots of blood firmly adhering to the palms. It therefore appeared that the effusions of blood did really occur spontaneously, and without the intervention of any violent means from without.'

During one of M. Warlomont's visits to Louise Lateau, he asked her to take about fifteen grammes of bread and thirty of infusion of coffee, which she did without any difficulty. She felt sick about ten minutes after taking it, but it remained on the stomach half-an-hour afterwards, when the commission left. It has, however, been asserted that persons worthy of credit had some hours afterwards seen the food and some blood in a basin, and Louise had declared that she had vomited it after the trial in question.

(To be continued.)

PRINCE ON STAPHYLOGRAPHY.

At a meeting of the St. Louis Medical Society, on November 28, Dr. D. Prince introduced the subject of staphyloraphy, in which he called attention to the following three points : 1. The employment of galvano-cautery to diminish the loss of blood, and further to add facility to the operation and certainty to the result ; 2. The introduction of automatic needles, both for the introduction of the platinum wire for cautery and for the taking of the final stitches for the closure of the fissure ; 3. A new interpretation of the functions of the muscles in the pillars of the fauces, from which he concluded that their division is not only useless, but also injurious to the future completeness of the function of the palate.

FIG. I.

The method of Galvano-cautery applicable to the soft palate. The field is as if upside down ; the soft palate is, for convenience, conceived as if in a line with the hard palate. A A, the fissure through the hard palate and the soft. b and C C, lines of incision in the hard palate. E E, platinum wire in position with the loop on the other side of the membrane to be divided, being thus hidden from view. The dotted line between the portions of the wire indicates the line of cautery incision. F F, silver tubes, with wood intervening, sliding down on the wires to the surface of the palate where the incision is to be made. The passage of the current is controlled by an interrupter in a pedal. The strength of the current is regulated by the depth to which the plates of the battery are immersed.

He introduced the subject by a brief notice of the nature of cleft palate, hard and soft, and referred to the operations of Fergusson and Dieffenbach.

He referred to the division of the pillars of the fauces, as practised by Fergusson, as endangering

the future perfection of function. Previously to the adoption of Fergusson's method, Dieffenbach had made vertical incisions in the soft palate; these do not interfere subsequently with the functional movements of the part.

Velpéau (Mott's translation, vol. iii. p. 396) says: 'Of the side incisions through the velum, one is made on each side of the cleft, plunging the bistoury in half an inch from it and half an inch distant from either end of the cleft. The bistoury is then carried, with a sawing motion, directly to the hard palate. Considerable blood flows; and the mouth must be washed frequently with cold water.'

Dieffenbach recommended that the parallel incisions should be made after the completion of the sutures. The dangerous hæmorrhage liable to occur led to the abandonment of this plan. The galvanocautery permits us to restore this proceeding of Dieffenbach, and to carry it so far to the lateral base of the palate as to make the incision most effectual, without fear of the loss of blood. Furthermore, we are able to make this the initiative proceeding in

operations upon the soft palate. By this means the automatic movements of the palate are annulled, and the paring of the edges of the fissure is performed with much greater facility. Even under ether, the half uvula on each side rises and falls with respiration, and the half-palate approximates and recedes. The movement, in a great degree, ceases after the vertical incision.

The incision made by Dieffenbach had for its object simply the relief of the strain upon the sutures, and was practised as the last step in the operation. With the cautery wire, and as a first step, it greatly facilitates the operation, at the same time that all possible strain upon the stitches is prevented. The cautery incisions are packed full of oiled paper, which is held there by the sutures, in order not only to take off the tension from the sutures, but really to crowd those surfaces together which are expected to unite. These stuffed openings, one on each side, will close up afterwards. The crossing of muscular fibres favours this closure.

On the other hand, the muscular fibres all pull

FIG. 3.

Dr. Black's improvement upon Prince's needle, being automatic. *A A*, a shaft with handle at one end, and hook, *B*, upon the other end, fenestrated at the place of the dotted line for the reception of the needle, *C*, which has an eye near its

point for the reception of the thread, *E E*. *D*, a shaft moving a short stilette in *B* which picks up the thread.

FIG. 4.

Another form of Black's improvement. *a a*, shaft with handle and curved needle-point as in fig 2. *b b b*, fenestrated slide for the reception of the point of the needle, *c*, holding the thread, *e e*. *p*, pasteboard showing the position of the needle having pierced a membrane with the stitch already picked up. *d*, the thumb-piece of a shaft moving a short stilette in the lower end of *b b b* which picks up and holds the stitch.

away from the median line, making a tendency to become larger instead of smaller. This pull upon the median line is sufficient, after union, to approximate the separated bony arch of the mouth, where there is, at the same time, an opening in the hard palate, making the fissure between the mouth and the nose narrower. This is a reason for closing the soft palate first and the hard palate afterwards.

Note was made of the physiological objection to the plan of Fergusson, of dividing the palatoglossus and palato-pharyngeus. It is found, by observation upon the movements of the curtain of the palate in halves, that the contractions of both these pairs of muscles approximate the sides of the cleft palate; in one case which was observed, causing the two halves of the uvula to come into contact. The mode of this will readily be understood by recalling the manner in which the tongue is protruded by the genio-hyo-glossus. So, while the palate is stiffened by the fibres of the tensor palati, the levator palati, the azygos uvulae, and by a few fibres of the palato-glossus and palato-pharyngeus, the main portions of these last two muscles engage in approximating the two halves. To cut these muscles is, therefore, physiologically absurd, besides endangering their future functional perfection. Without the action of the palato-pharyngeus, the perfect articulation of the gutturals is impossible. The loss of the function of the palato-glossus would not be seriously felt in articulation.

In an operation beyond the reach of touch by the fingers, great importance attaches to the quality of the instruments employed. The conception of the employment of galvano-cautery and its practice developed the necessity for an instrument capable of the more accurate introduction of a thread or wire than any with which Dr. Prince was acquainted. The needle represented in fig. 2 was exhibited, having a slide with a fenestra closing down over the point.

The possibility of knowing the point of entrance, which is out of sight, and that the point of exit will correspond, is achieved. This is important in introducing the platinum wire for cautery—the parts at the lateral base of the palate being thick with much connective tissue between the muscular layers. The convenience of the same instrument for the sutures, for permanent retention, was also made clear.

Dr. Black, a dentist of Jacksonville, has made an improvement upon this needle, by which a pick-up pin is made to catch and hold the stitch, so that certainty of position and ease of execution are combined. The needles are made in two forms—in one the needle recedes from the operator, and in the other it approaches him (Figs. 3 and 4).

ANATOMY AND PHYSIOLOGY.

VULPIAN ON THE ACTION OF JABORANDI AND ATROPIA ON PERSPIRATION.—M. Vulpian (*Progrès Médical*, February 13, 1875) says that it has been experimentally ascertained that atropia checks the flow of saliva from the submaxillary gland by paralysing the terminal filaments of the chorda tympani. Heidenhain has shown, further, that the vaso-inhibitory (or vaso-dilator) fibres contained in the chorda are not affected by the drug; for excitation of the glandular filament of the chorda (*i.e.*,

faradisation of the lingual before the glandular filament is given off from it) accelerates the circulation through the gland quite as well after the administration of atropia as before it; in the former case, however, it no longer succeeds in causing a single drop of saliva to flow from Wharton's duct. Lastly, we may conclude that atropine does not act directly upon the secreting cells; for the same slight exudation of saliva is caused by electrical stimulation of the cervical sympathetic in a curarised dog, whether it be under the influence of atropine or not.

Now if either muscarin or jaborandi be injected into the femoral vein of a curarised dog, profuse salivation ensues; this may be immediately arrested by the subsequent injection of atropia. What we already know of the action of the latter alkaloid, authorises us to conclude that both muscarin and jaborandi excite salivation by stimulating the terminations of the secretory fibres of the chorda tympani, and not in virtue of any action on the sympathetic.

By putting together what is known about the influence of atropia and jaborandi on the salivary secretion, and about their mutual antagonism as regards the perspiration, Professor Vulpian endeavours to throw light on the nature of the influence exerted by the nervous system on the latter function. After referring to the experiments of Bernard, who showed that section of one cervical sympathetic in the horse was followed by sweating of the head and neck on the same side, while stimulation of the upper end of the divided cord arrested the secretion, he suggests that the sweat-glands may probably stand in much the same relation to the vaso-motor system as the submaxillary gland. Moreover, since atropia and jaborandi do not influence the submaxillary secretion through the sympathetic nerve, their corresponding action on the perspiratory function should not be attributed to any stimulation or paralysis of vaso-motor fibres. We may legitimately suppose that the functional activity of the sweat-glands is controlled by some nervous mechanism analogous to the secretory filaments of the chorda tympani in the case of the submaxillary gland.

He adds a hypothesis concerning the mode of action of the chorda tympani. It is not needful, he thinks, to suppose that its terminal filaments are in direct relation with the secreting cells. We may regard the secretion of the submaxillary gland as being under the control of intrinsic inhibitory ganglia. The degree of activity of these ganglia is inversely proportionate to the functional activity of the secreting tissue. The glandular filaments of the chorda tympani are intimately connected with these regulating centres; stimulation of those fibres arresting the action of the ganglia, while their paralysis leaves the ganglia to operate unchecked. Jaborandi and muscarin paralyse the inhibitory ganglia; they do what may be done by electrification of the chorda tympani. Atropia, on the other hand, exalts the normal activity of the ganglia; its action being analogous to section of the chorda tympani.

LANGLEY ON THE ACTION OF JABORANDI.—Under the title of 'Preliminary Notice of Experiments on the Physiological Action of Jaborandi,' Mr. J. N. Langley, of St. John's College, Cambridge, sends a very interesting and important communication to the *British Medical Journal* of February 20. He finds that, injected under the skin, jaborandi excites through its influence on the spinal cord, tetanic convulsions similar to

those of strychnia. In dogs and rabbits this effect was not observed, though this difference may depend on the dose.

The drug, introduced into the jugular vein, at once lowered the pulse in dogs and rabbits. The pulse was reduced to one-third its previous rate. In the frog the drug arrested the heart in diastole, but atropia caused the heart to beat again. He concludes that jaborandi stimulates the inhibitory fibres of the pneumogastric, but does not rapidly exhaust them. In the dog and rabbit, jaborandi caused slight decrease in arterial pressure.

Injected under the skin of a frog's back, it dilated the arteries, capillaries, and veins, and retarded, nay, even arrested the circulation of the web of the foot, whether the sciatic nerve were intact or divided. Injected into the jugular vein of a rabbit, after section of the sympathetic of one side, jaborandi first contracted and then dilated the vessels of the ear; the dilatation was greater than on the side where the sympathetic was left uncut. He concludes, therefore 'that paralysis of the normal vaso-motor influence does not thus seem to be one of the most prominent characteristics of jaborandi.'

As jaborandi caused increased secretion of the submaxillary gland after section of the chorda tympani, he concludes that the drug acts on the periphery of the nerve. It rapidly exhausts the gland. Section of the sciatic nerve appeared to have no influence over the secretion of the skin of the leg excited by jaborandi.

Mr. Langley points out the similarity between the action of jaborandi and of physostigma.

PATHOLOGY.

RENAUT ON CUTANEOUS ERYSIPELAS AND OEDEMA.—A recent contribution to the anatomical and clinical study of erysipelas and oedema of the skin, by Dr. J. Renaut, has been summarised in the *Revue Médicale de l'Est*, January 15, 1875. The distribution of the lymphatics of the skin is first discussed. This is best shown by the superficial subcutaneous injection of a watery solution of Prussian blue by means of a Pravaz's syringe introduced obliquely, so that, the point of the syringe being visible through the epidermis, the fine plexus of the superficial lymphatic capillaries is thus displayed, the colouring matter penetrating from these into the deeper layers, where larger trunks, provided with valves, abound.

Vertical sections of skin thus injected show the lymph-capillaries forming irregularly dilated channels with angular outlines, the most superficial net-

work being below the level of the papillæ and their blood-capillaries, occupying mainly a position intermediate between the superficial vascular plexus whence the papillary loops are given off, and the wider meshed network of blood-vessels surrounding the cutaneous glands. A lymph-capillary is formed simply by the spaces left between the connective tissue bundles of the dermis, bounded by flat epithelial cells, each having a large vesicular nucleolated nucleus. The transition from these simple lymphatic spaces to the deeper trunks provided with definite walls of connective tissue and smooth muscular fibre, is very gradual.

The lesions produced in the skin by erysipelas are simply those of inflammation, of a dermatitis (lit. *dermitis*). Thus there is an infiltration of the skin with white corpuscles by diapedesis from the vessels, corresponding to inflammatory oedema, at first limited to the vicinity of the dilated blood-vessels, and later distributed throughout the dermic tissue. Absence of abundant fibrinous exudation distinguishes erysipelas from abscess; but the transuded liquid is more coagulable than in simple oedema. The cellular infiltration may occupy all the meshes of the dermis, usually it is collected around the blood-vessels, hair-follicles, and sweat-glands. The lymphatics of the dermis must be regarded as the usual destination of the cells. In the deep layers of the dermis there is proliferation of the flat cells coating the connective tissue-fibres, the resulting elements being larger in size than the migrated white blood-cells, besides possessing small vesicular nuclei. There is also true inflammation of the adipose tissue, with proliferation of its elements. In about one-fourth of the cases the larger lymphatics are inflamed, while in the lymphatic glands there is proliferation of both the lymph-corpuscles and of the fixed stromal cells. Erysipelas ends by simple resolution, the infiltrated cells being resorbed or degenerating, or it terminates in suppuration. In the latter case islets of pus-corpuscles occur, which eventually undergo granular and fatty degeneration, and are probably taken up by the lymphatics.

M. Renaut concludes that there is nothing distinctive about the cutaneous lesion in erysipelas; the dermatitis scarcely differing from that induced by experimental irritation. He urges, however, that these changes must only be regarded as part of the disease, the characteristics of which must not be based simply on the cutaneous lesion any more than upon any one of its symptomatic manifestations taken apart.

Ranvier has shown that, in the different varieties of passive as in inflammatory oedema of the skin, there is an infiltration of white blood-corpuscles into the meshes of the connective tissue; the transit of corpuscles and serum being due to increased blood-tension in the capillary networks; this condition arising from simple atony of the vessels apart from venous obstruction. (See Cornil and Ranvier, *Manuel d'Histologie Pathologique*, p. 445.) Paralysis of the muscular fibres of the vessels by destruction of vaso-motor nerves suffices for this. This refers to primary oedema, but the cutaneous oedema following prolonged oedema of the cellular tissue has been hitherto but little studied. Here, in addition to dilatation and engorgement of the blood-vessels, surrounded by exuded white corpuscles, which also occur in groups between the fibrous bundles of the dermis, there is invariably a dilatation of the lymphatic capillaries, forming stellate lacunæ, many of

which are stuffed with desquamated epithelium. Hard or hypertrophic œdema consists in a chronic and subacute inflammation of the skin, with consequent hyperplasia of its tissues; it is always accompanied by dilatation of lymph-capillaries, and even of the larger lymphatic trunks and afferent vessels of the glands, which may also become chronically inflamed and converted into fibrous tissue; stagnation of lymph occurs in the dilated vessels and later in the connective meshwork, so that chronic cutaneous œdema may end in elephantiasis hypertrophy. There is thus a striking analogy between the lesions produced by chronic œdema and by erysipelas. M. Renaut believes that this anatomical likeness serves to explain the frequent association of the two affections, erysipelas leading to œdema, or chronic cutaneous œdema favouring the development of erysipelas; and he supports his view by an analysis of clinical facts.

The relations between œdema and erysipelas on the one hand and lymphangitis on the other, are also discussed. Inflammation of the lymphatic trunks is to be regarded as an epiphenomenon of erysipelatos dermatitis. Lymphadenitis is more constant, and shows the active part played by the lymphatic system in the disease; the inflamed glands, as M. Raymond has stated, acting as temporary barriers to the absorption of septic virus. Œdema of the lax muscular tissue and of the skin may equally result from lymphangitis and from acute or chronic lymphadenitis.

SIDNEY COUPLAND, M.D.

KEY ON SPHENO-OCCIPITAL ECCHONDROSIS.—Professor Axel Key describes in the *Hygiea* for 1874 (abstract in *Nordiskt Medicin. Arkiv*, vol. vi. no. xxxii.) a growth found during the *post mortem* examination of a man who had died of cerebral abscess. The tumour, which was 0.54 inch long and 1.6 inch broad, presented a greyish gelatinous appearance; it was soft, and of fluid consistence in the centre. It arose from a point corresponding to the junction between the sphenoid and occipital bones, and was attached to a small bony projection which perforated the dura mater. The tumour presented both to the naked eye, and microscopically, the ordinary characters of the rather rare form of ecchondroma which is developed in the original site of the sphenoccipital synchondrosis. At several points, there seemed to be a fusion of diverticula from adjacent cells, giving rise to peculiar structures; and there appeared to have been a process of fusion at its base. The tumour did not produce any symptoms during life, in consequence, Herr Key believes, of its having sufficient room in the subarachnoid space to grow without pressing on the brain.

BULL AND HANSEN ON CANCER OF THE STOMACH, WITH SECONDARY DEPOSITS ON THE LIVER AND LUNGS.—Bull related to the Bergen Medical Society (*Norsk Magazin för Lægevidenskaben*, series iii. vol. iv., abstract in *Nordiskt Medicin. Arkiv*, vol. vi. no. 32) the case of a man, aged fifty-nine, who had always appeared to be strong and healthy; he led a regular life, and was of powerful frame. In the autumn of 1872, and again in the spring of 1873, he passed blood in his urine, but without pain. After this he lost his appetite, his strength gradually diminished, he became emaciated, and died in May, 1873. A *post mortem* examination was made by G. A. Hansen. Two cancerous ulcers were found at the pylorus. The liver contained numerous large

somewhat firm metastatic nodules. The lymphatic glands below the liver and behind the stomach were infiltrated with cancer. On the surface of both lungs were numerous stellate scirrhous contractions, surrounded by small flat nodules; and from the cicatricial depressions, wedge-shaped infiltrations passed into the substance of the lungs. There were large calculi in the pelvis of both kidneys, and these organs were remarkably atrophied.

A point of interest in this case is the very slight amount of functional disturbance, in spite of the long duration of the disease. A. HENRY, M.D.

MEDICINE.

CHADWICK ON A CASE OF IMMEDIATE TRANSFUSION.—Dr. James R. Chadwick relates (*Boston Medical and Surgical Journal*, Jan. 14, 1875) the case of a woman, thirty-two years old, who, eleven weeks before admission into the Massachusetts General Hospital, had given birth to her second child. The labour was easy and natural, but was accompanied by smart hæmorrhage; and this recurred frequently till within two weeks of her admission, reducing her from robust health to extreme anæmia with constant headache, constipation, etc. Iron, generous diet, etc., having been tried for a week, Dr. Minot, in whose ward she was, found that she was sinking, and requested Dr. Chadwick to perform transfusion, which he had previously declined to do until less severe measures had had a fair trial. On June 3, at 6 P.M., the pulse was 118, respiration 30, temperature 102.8°, and there were other serious symptoms. On June 4, the operation was performed with Aveling's instrument for direct transfusion, as supplied by Messrs. Krohne and Sesemann of London. The blood-giver, Dr. J. J. Putman, laid his left arm beside the patient's right one, and the patient's median basilic was opened by a V-shaped incision, access to it being first gained by a transverse incision through the skin. The afferent nozzle was then taken out of the basin of warm water, care being taken not to let the water escape, and introduced. A direct longitudinal incision was made into Dr. Putman's median cephalic vein, but the efferent nozzle could not be introduced, and it was therefore introduced into the radial; the afferent nozzle had meanwhile become choked, and required cleansing and re-introducing. The two were then connected by an India-rubber tube full of warm water, and the operation performed, the bulb being filled and emptied twenty-two times; this, according to the printed directions sold with the instrument, should have given five and a-half ounces; but eleven ounces were transfused. The bulb filled badly during the last two times, apparently from anæmia (induced) of the blood-donor. The immediate result was to reduce the pulse to 104, to bring colour to the patient's lips and cheeks, and to produce some back-ache and heart-beat. Some difficulty was experienced in stopping the hæmorrhage from the vein; but when all was finished, she felt stronger

and better. Shortly a severe rigor, lasting an hour, came on, the temperature rose to 106.4°, the pulse to 134, and there was nausea and vomiting; the latter was severe two hours after the rigor, and the bandages became loose, and about five ounces of blood escaped; a ligature was therefore applied to the vein. Three hours later the patient was delirious, then comatose, in which condition she remained during the night. She was conscious in the morning, but gradually sank, and died the next night at 7 P.M.

The necropsy, twenty-six hours after death, showed general anæmia, acute internal pachymeningitis, increased fluid in the pericardium, spotted fatty degeneration of the heart, œdema of the lungs, etc. No thrombi or signs of froth or air-bubbles could be found anywhere. The urine in the bladder was slightly albuminous and smoky, and contained hæmatin.

Dr. Chadwick, in remarking on the case, points out that neither the symptoms before death, nor what was seen *post mortem*, pointed to any cause of death except general fatty degeneration. This he considers due directly to imperfect nutrition from repeated large losses of blood, occurring too rapidly to give nature time to repair the extraordinary waste. He points out that in such cases the vessels are full of poor watery blood, and that transfusion increases the vascular tension to an extent dangerous to the already degenerated heart, which has, besides distension, extra work to do in forcing the blood into narrowed channels. He considers this fatty degeneration of the heart to be nearly certainly present in this class of cases, and they are therefore not so

suitable for transfusion as cases where the loss of blood has been rapid, and the vessels are empty and collapsed. He states that Ponfick has described this form of spotted fatty heart as common in women dying after hæmorrhages in childbed, and that Perl has artificially induced a similar condition in dogs by repeated bleedings. These views had led him to decide only to transfuse six ounces of blood; but the wrong description of the capacity of the bulb caused the transfusion of eleven ounces, and hastened the fatal termination, which, however, he considers inevitable in such a case. He advocates repeated small transfusions in such cases, or letting the poor blood flow away from the other arm while the new blood is passing in. Aveling's instrument worked well. In conclusion, he questions the propriety of attributing the anæmic systolic bruit to an impoverished condition of the blood, and thinks it more likely that it is symptomatic of fatty heart. Such a bruit was heard in this case before the operation, and remained unchanged to the end.

J. KNOWSLEY THORNTON.

EBSTEIN AND MÜLLER ON THE TREATMENT OF DIABETES MELLITUS BY CARBOLIC ACID, WITH REMARKS ON THE USE OF SALICYLIC ACID IN THIS DISEASE.—Eight columns of the *Berliner Klinische Wochenschrift* for February 1, 1875 (no. 5), are occupied by a paper in continuation of one by the same authors in no. 49 of that journal for 1873. Whilst still recommending carbolie acid for many cases of this disease, they candidly admit instances of failure, especially when there is only a very small percentage of sugar. In some of these

Sex.	Age.	Duration of Symptoms.	Quantity of Urine in twenty-four hours.	Percentage of Sugar.	Treatment.	Results and Remarks.
F.	46	5 months?	8 to 10 pints.	1.25, sometimes none.	5iv carbolie acid	Results of treatment negative. Had double optic atrophy, with left-sided symptoms, such as headache, deafness, etc.
M.	34	From spring of 1872.	5 to 7 pints.	3 to 4.	Restricted diet, and glycerine. Tartaric acid, carbolie acid, and iron. Change of air. Carlsbad iron and cod-liver oil. Salicylic acid, 3j nearly in four days.	Change of air seemed to do a little good at one time. He gained weight whilst using glycerine. Carbolie acid and salicylic acid seemed useless. So did Carlsbad water.
M.	60	6 or 8 months.	5 to 7 pints.	4 to 5.	Carlsbad water. Carbolie acid, 3iv.	No result from either.
M.	?	Not stated, but 3 or 4 years at least.	Not stated.	4 to 5.	Carlsbad (residence). Carbolie acid, seven or eight grs. a day. Salicylic acid, about three grs. in all.	Carlsbad and carbolie acid both diminished the sugar almost to nothing. Salicylic acid was useless.
M.	34	1½ years.	Not stated.	Not stated.	Carbolie acid, 3iv in eighteen days.	Relief. Had double cataract and was impotent.
F.	52	1½ years.	17 pints.	6 per cent.	Antidiabetic diet, and five grs. carbolie acid per diem.	Great relief. She had a large number of painful subcutaneous tumours [neuromata.] Ptosis and paresis of muscles of right eye, from an injury?
M.	48	2½ years.	Not stated.	Very large quantity of sugar.	Carbolie acid.	Complete cure of glycosuria. Had phthical symptoms. Had chronic bronchitis and dyspepsia.
M.	70	4 years.	Not stated.	4 to 5.	Restricted diet. Carlsbad and Kissingen Spas. Carbolie acid, 3ij in all.	Temporary cures with all these remedies. Effect of carbolie acid very marked.
F.	54	2 years.	14 to 17 pints.	3 to 4.	Restricted diet, and carbolie acid, 3iv.	All sugar disappeared. Relapse, and again relief by same means.
M.	47	2 or 3 years?	Not stated.	5 per cent.	Carbolie acid. Salicylic acid, fifteen grs. Carbolie acid, again, fifteen grs.	Relief from carbolie acid. No effect at all from salicylic acid. All sugar disappeared in three days with second administration of carbolie acid.

Carlsbad water was serviceable. The chief interest of the paper lies, however, in the trials of salicylic acid, which they were induced to make by the experiments of H. Kolbe (*Journal für Praktische Chemie*, x. Jahrgang, 1874), showing many interesting analogies between this substance and carbolic acid. Thiersch also has shown that it may be used in surgery with all the good effects and none of the unpleasant smell of phenol. [Salicylic acid ($C_7H_6O_3$) may be prepared by passing carbon dioxide into phenol containing small pieces of sodium :

By dry distillation, salicylic acid is again converted into phenol or carbolic acid. Vide *Fownes's Chemistry*, edited by H. Watts, pp. 792, 820, etc.] In three instances, the authors found no good effects from the use of salicylic acid. For details of these, the reader is referred to the original, but the brief outlines are as follows. (See table on previous page.)

They point out that, even when carbolic acid does not cure, it seems, when well diluted, not to prove in the least injurious. Patients do not complain so much of the taste as might be expected, especially if a little peppermint-water be added. As glycosuria is clearly a symptom rather than a disease, no one method of treatment is likely to be serviceable. Carbolic acid seems to act by its remarkable power of preventing fermentation. [The number of cases, and the quantity of salicylic acid given, seem to the reporter too small to permit any definite conclusions as to its effect to be drawn.—*Rep.*]

W. BATHURST WOODMAN, M.D.

GERHARDT ON ACUTE INFECTIOUS DISEASES.—Dr. Gerhardt has grouped together, under the title of contribution to the natural history of acute and contagious diseases, a considerable number of interesting facts, which are published in the *Deutsches Archiv für Klinische Medicin*. In observing the variations in the duration of the period of incubation in different febrile diseases, it is interesting to mark how constant it seems to be in some, whilst in others it is variable or not well defined. In measles, small-pox, varicella, roseola, typhus, and mumps, the period of incubation is fourteen days. In typhoid fever it is from two-and-a-half to three or four weeks, the average being three weeks; in scarlatina from five to seven days; in syphilis from four to six weeks. Certain causes may induce variations in the length of the incubatory period, as, for instance, the external temperature. Vaccine becomes developed more rapidly in the summer, and the vesicles of small-pox appear more quickly in parts exposed to heat. The way in which the organism is impregnated has also an effect on the duration of incubation. It is recognised that inoculated small-pox has a shorter period of incubation than when the disease is taken through the medium of the air-passages.

Gerhardt reports a case in which the contagion of scarlet fever seems to have been communicated by a surgeon's knife (?), and in which the disease appeared after four days' incubation.

It is probable that the administration of medicines may influence the duration of the incubation, as observed in syphilis, in which mercury certainly produces an effect of that kind. It is scarcely probable that the incubation may be influenced by the quantity

of virus; but it is probable that the particular conditions in which the virus is developed may have some action. Gerhardt believes that examples of relapse have been observed in all forms of acute contagious diseases. Cases of relapse in scarlatina have been described by different writers, the relapse generally occurring in the course of the third week. Relapses have also been observed in measles, roseola, and small-pox; and Dr. Gerhardt has also noted one in a case of mumps.

SURGERY.

BERKELEY HILL ON GLEETS.—In the *Lancet* of February 13, Mr. Hill describes at some length the etiology, pathology, symptoms, and treatment of gleets. He divides them into two classes—urethral and prostatic, and these again into several subdivisions. In the treatment of the common form of urethral gleet, where there is little tenderness of the urethra or resistance to the passage of a sound, Mr. Hill advises the use of the French soluble bougies (Reynal's), one to be passed every night, and left *in situ*; the patient should also take twenty or thirty grains of powdered cubebs daily. If, however, the discharge be white and somewhat thick, and, on passing a sound, there be found to be tenderness and slight resistance at certain fixed points, Mr. Hill injects, through a bulbous-headed hollow sound, a few minims of a solution containing from ten to twenty grains of nitrate of silver to an ounce of water, opposite each of these tender spots, beginning with the most distant. The bladder should first be emptied, and the patient should retain his urine for some hours after the operation. Usually this treatment increases the discharge for two or three days, and it then diminishes or ceases altogether. If necessary,

the operation may be repeated in a week, a mild astringent injection being used in the interval; or the passing of a bougie every second or third day for a fortnight will often complete the cure. In cases where more decided inflammatory thickening of the urethral mucous membrane is shown by marked resistance to the passage of the sound, Mr. Hill introduces a bougie, the end of which is coated with peroxide of mercury or nitrate of silver suspended in cocoa-butter, in the proportion of five grains to an ounce; or he injects a stronger solution of nitrate of silver.

The treatment of gleet depending on subacute or chronic prostatitis is, as Mr. Hill confesses, less satisfactory. If the discharge be whitish and opaque, he gives frequent small doses of copaiba; if it be thinner, and if the prostate be not tender when pressed by the finger, tincture of cantharides, one or two drops four times a day, is most beneficial. The regulation of the diet is most important, and hip-baths are useful; but Mr. Hill has little faith in the value of counter-irritation applied to the perinæum.

HUTCHINSON ON THE USE OF THE TREPHINE. Speaking of the treatment of compound fractures of the cranial bones, Mr. Jonathan Hutchinson says (*Medical Times and Gazette*, Feb. 13) that when, although only a fissure is visible externally, there is reason to suspect that there may be splintering of the inner table to a much greater extent, *e.g.*, in 'punctured fractures,' the case should be watched with additional circumspection; and, if headache of a fixed and persistent character should come on, the trephine should be used. There is, of course, need of great care in the examination of this symptom of headache; but supposing that a patient, who has been quite comfortable during the first few days, should begin to complain of very severe pains beneath the seat of injury, and that the pain should be persistent and sufficient to keep him awake at night, the propriety of exploration would certainly be indicated.

Mr. Hutchinson is strongly of opinion that, by waiting for the symptoms usually mentioned as indicating the propriety of interference, the chance of a favourable result is greatly lessened, *e.g.*, when rigors occur the case is almost hopeless. The early symptoms of intracranial mischief are general feverishness, loss of appetite and headache, and of these, headache, if cautiously estimated, is undoubtedly the most important. He relates cases illustrating his practice, and sums up the result of his experience as follows. 'I have never regretted the performance of primary trephining, and have often regretted its omission.'

In cases of simple fracture, on the other hand, even though there be depression of bone, Mr. Hutchinson deprecates active interference. The relative danger of simple and compound fractures of the skull does not differ from that of similar lesions of other parts; 'the danger is not so much the fracture of the bone as its being exposed to the air; if then there be no admission of air we scrupulously avoid its introduction, and whether the fracture be depressed or not, we equally decline to operate.'

ENSOR ON DISTAL OPERATION FOR ANEURISM OF THE INNOMINATE ARTERY.—Mr. Fred. Ensor, surgeon to the Port Elizabeth Hospital, South Africa, reports, in the *Medical Times and Gazette* for February 6, a case in which he ligatured simul-

taneously the carotid and subclavian, in the hope of curing an aneurism at the root of the neck, which he supposed to arise from the innominate artery. The patient was a Kaffir Hottentot; he suffered from considerable dyspnoea and dysphagia, and was in constant pain. The operation appears to have temporarily relieved these symptoms; but at the time of the report, six weeks after the operation, the tumour was inclined to enlarge, the man was again suffering from dyspnoea on exertion, and could only swallow semi-fluid food. [It seems a pity that Mr. Ensor did not postpone the publication of this interesting case a little longer, and perhaps he might have been able to explain the cause of the failure.—*Rep.*]

J. W. LANGMORE, M.D.

LABBÉ ON TAPPING AS AN AID TO THE REDUCTION OF HERNIA.—In the Society of Surgery at Paris (*Gazette des Hôpitaux*, January, 1875) a discussion recently arose on the above method of diminishing the tension of a hernia before reducing it. M. Labbé related two cases where this plan had been adopted by M. Ollivier of Rouen.

In the first case, the hernia had been strangulated twenty-four hours; chloroform was administered, and taxis attempted without success. Further proceedings were delayed until the next day, when, by tapping the sac, some spoonfuls of brownish liquid were withdrawn; again attempts to reduce failed, and herniotomy was performed. The gut was found covered with false membranes, and the mesentery twisted. Death followed seven or eight hours later.

The second case was one of large umbilical hernia strangulated for fifteen to eighteen hours. The patient had an organic affection of the heart, so Ollivier decided not to give chloroform. The hernial tumour consisted of two lobes, one red and inflamed, the other normal and translucent. He punctured the sac, and withdrew a large wineglassful of liquid and reduced the hernia easily. The patient did well.

A discussion followed the narration of the cases. M. Labbé maintained that in cases of hernia the patient should not be left until the hernia is reduced; that puncture either of the sac or of the knuckle of intestine by a fine needle is a harmless operation and may facilitate the return of the protruded viscus. M. Després was against the puncturing hernial tumours as waste of valuable time, and urged that all strangulated herniæ should be operated upon as soon as possible, and when twelve hours have elapsed after strangulation, nothing should delay herniotomy. Any further attempt to succeed by taxis in such cases, he said, greatly increases the gravity of the prognosis. Labbé urged that for very large herniæ it is permissible to wait some little time; but with small plainly strangulated herniæ the simple taxis, prolonged, and aided by chloroform, should be followed by operation immediately. M. Lefort was content to apply this rule to crural herniæ, but not to inguinal, where no delay should intervene on any account.

BERKELEY HILL.

GUILLAUMET ON THE TREATMENT OF ATONIC WOUNDS AND CHRONIC ULCERS BY SULPHURET OF CARBON.—M. Paul Guillaumet, house-surgeon at the Saint-Lazare Hospital, laid before the meeting of the Société de Thérapeutique, on January 27, the details of some cases collected in Dr. Costilhès' wards. Some of them were cases of ulcer which had resisted all kinds of treatment, and were favourably modified by sulphuret of carbon. M. Guillaumet is of opinion that sulphuret of carbon

is a very powerful cicatrisant. Its action is limited and rapid, entirely local, and does not bring on any of the accidents which follow the prolonged inhalation of the vapours of this substance. There is sometimes acute pain at the moment of application, but it rarely lasts longer than from twenty to sixty seconds, and is immediately followed by an anæsthetic period which lasts several hours. The sulphuret acts upon wounds of different nature and origin, such as those connected with syphilis, scrofula, and diphtheria, and changes them all beneficially. It is a valuable agent in the treatment of chronic and atonic wounds and ulcers. As this substance is extremely volatile, and has a very disagreeable odour, M. Guillaumet gives very precise directions for its use. The bottle containing the pure sulphuret of carbon should be held very near the wound; a pledget of lint should be steeped in the liquid, pressing out the surplus of the medicament on the edge of the bottle; then the pledget should be quickly and lightly passed over the surface of the wound which should immediately be covered up with finely pulverised subnitrate of bismuth. The same method is pursued for all wounds, including those of the neck of the uterus. The powder of bismuth plays the part of an insulator, and acts as a protecting covering against the too rapid evaporation of the drug, increased by the heat of the body.

MATERIA MEDICA AND THERAPEUTICS.

LISLE ON THE INTERNAL ADMINISTRATION OF SEA-WATER.—Lisle (*Bulletin Général de Thérapeutique*, February 15, 1875) says that the neglect of sea-water as an internal remedy is due partly to the difficulty of masking its nauseous taste, partly to that of preserving it for any length of time without decomposition. These difficulties were overcome by Pasquier in 1843, who filtered the water, and then saturated it with carbonic acid. His process was an expensive one, and never became popular, notwithstanding Roger's very favourable report upon it. That report stated that effervescing sea-water acted as a very efficient saline purgative; that it was taken by patients without any repugnance; and that, in doses less than purgative, it appeared to exercise a favourable influence on persons suffering from scrofulous maladies. The purgative properties of sea-water were known to the ancients and utilised by them, as is proved by the following extract from Pliny (*Hist. Nat.*, xxxi. 6): 'Inveteratur quod vocatur thalassomeli, æquis portionibus maris, mellis, et imbris; ex alto et ad hunc usum advehunt, ficulique vase et picato dunt. Prodest ad purgationes maxime sine stomachi vexatione, et sapore grato et odore.' Lisle's experiments lead him to the

conclusion that, besides being an useful purgative, sea-water acts as an alternative in all such cases as are benefited by saline mineral waters like those of Nauheim, Soden, Homburg, etc. He finds that its continued use increases the appetite, facilitates digestion, quickens nutritive changes, and augments the proportion of red corpuscles in the blood. Accordingly he recommends it: (1) during convalescence from acute diseases; (2) in the apyretic forms of dyspepsia; (3) in neurosis associated with impoverishment of the blood; (4) in the scrofulous and tuberculous diathesis; (5) in diabetes. Sea-water may be agreeably administered in bread, in the form of a syrup, or in that of an elixir. Bread made with sea-water can only be procured at the seaside; it is very palatable, and contains nearly five grammes of the mineral constituents of the water in each pound. The syrup is prepared by mixing 250 grammes of sea-water with a sufficiency of sugar and distilled water to make 500 grammes. Each table-spoonful of the syrup contains about twenty-five centigrammes ($3\frac{1}{2}$ grains) of the saline residue of sea-water; from two to five table-spoonfuls may be taken daily. The formula for the elixir is: sea-water, 200 grammes; rum, 200 grammes; sugar and distilled water up to 500 grammes. The dose at first is a table-spoonful three times a day.

To the obvious objection that a pharmaceutical mixture of the saline constituents of sea-water in their due proportions would serve the same remedial purposes as the sea-water itself, Lisle replies that the efficacy of all natural mineral waters is very much greater than that of their manufactured counterparts; the testimony of those who have instituted comparative trials being all but unanimous on this point.

MAYET ON FRUIT IN THE DIETARY OF DIABETIC PATIENTS.—Mayet (*Gaz. Médicale de Paris*, February 8, 1875) gives the mean result of a number of analyses undertaken in order to determine the proportion of sugar contained in various fruits, with a view to ascertain how far the addition of such fruits to the diet of diabetic patients may be allowable. It had already been shown by Buignet that many ripe fruits, such as apricots, peaches, plums, and strawberries, contain cane-sugar mixed with a variable proportion of inverted sugar; other fruits, among which are grapes, cherries, gooseberries, and figs, containing inverted sugar only. In relation to glycosuria, the two varieties of sugar are equivalent. Accordingly, the cane-sugar was in every case converted into inverted sugar by the action of dilute sulphuric acid, before the saccharine strength of the fruit was determined by means of Fehling's solution. The following are some of the results obtained. Raisins and dried figs yield from 71 to 76 per cent. of sugar; prunes, 42 per cent.; sweet cherries, 16 per cent.; acidulous cherries, 10 per cent.; garden strawberries, 12 per cent.; wild strawberries, 9 per cent.; oranges, 10 per cent.; gooseberries, 8 per cent.; plums and peaches, 10 to 12 per cent.; grapes, 16 per cent. Many fresh fruits, therefore, contain about 10 per cent. of sugar. The daily addition of 100 grammes of such fruit to the diet of a diabetic patient (100 grammes correspond roughly to twenty-five cherries, five table-spoonfuls of wild strawberries, 160 gooseberries, three or four large plums) would not materially increase the amount of glucose to be eliminated, while adding in a very marked degree to his comfort. E. BUCHANAN BAXTER, M.D.

RIEDEL ON THE THERAPEUTIC ACTION OF JABORANDI.—Dr. F. Riegel commences a paper in the *Berliner Klinische Wochenschrift*, February 8 and 15, 1875, by remarking that hitherto no observations on this drug have been made in Germany. He then gives a full account of the observations made in France. These writings have already been fully noticed in this journal.

He records ten observations made on patients suffering from different complaints. The temperature was taken in three cases. One of these was feverish, his temperature being 101° . The other two were free from fever. Dr. Riegel confirms the statements of previous writers, and adds nothing to our knowledge. The temperature fell during the sweating, the fall reaching respectively $1^{\circ}4'$ — $0^{\circ}9'$ — $0^{\circ}4'$ Fahr. The pulse was generally quickened, but in the fever cases, as the reporter found in his observations, the pulse fell. From sphygmographic observations, Dr. Riegel concludes that the jaborandi causes arterial relaxation and increased force of the heart's contractions. Sickness, giddiness, disorder of sight, glimmerings before the eyes, and strong desire to pass urine, were noticed in some of the cases.

SYDNEY RINGER, M.D.

TRASBOT, DUJARDIN-BEAUMETZ, AND GUBLER, ON MONOBROMIDE OF CAMPHOR.—M. Trasbot, one of the professors at the College at Alfort, has made some experiments on animals with the bromide of camphor, the results of which are at variance with those described by M. Bourneville. M. Trasbot first administered bromide of camphor to dogs attacked with epilepsy or chorea, and did not obtain any alleviation of the nervous symptoms. The dose given at first was ten centigrammes, afterwards increased to fifty centigrammes, and even to a gramme. In another series of experiments instituted with the object of studying the action of bromide of camphor, he never observed the slightest tendency to sleepiness, nor the least lowering of the temperature. On the contrary, this drug, in doses of from thirty centigrammes to one gramme, produced very decided symptoms of excitement and true convulsive fits, precisely similar to those induced by strychnine; so that, according to these experiments, bromide of camphor must be considered as a tetanic poison. M. Dujardin-Beaumont (*Bulletin Général de Thérapeutique*, February 15), has administered bromide of potassium many times in hysteria; but, in consequence of the difficulty of arriving at the truth with hysterical patients, his results are by no means conclusive. The results were perfectly nugatory in epilepsy; but in genito-urinary affections, such as spermatorrhœa, the bromide of camphor acts more as a camphorated preparation than as a bromide. M. Beaumont used Dr. Clin's dragées in all his trials. They each contain ten centigrammes of the active substance, and from one to ten daily were given. M. Constantin Paul obtained no results from the administration of bromide of camphor in a case of convulsive hysteria. M. Gubler has also treated four cases of hysteria without any marked improvement; he observed that the bromide of camphor, which, however, is a very stable compound, does not pass by the kidneys. The employment of nitrous nitric acid never showed the presence of bromine in the urine. M. Gubler on this subject, however, notes the influence of certain bodies, which he calls vector bodies, and which assist the passage of certain substances through the glands; thus iron does not pass

by the saliva, yet, associated with iodine, it is found in the secretion of the salivary glands. Camphor doubtless has a contrary function; as it does not pass by the kidneys, it prevents the passing of the bromide into the urine.

CLERMONT ON SOLUBLE ARSENIATE OF IRON.—Clermont (*Union Médicale*, February 6, 1875) recommends the substitution of a soluble ferrous arseniate for the insoluble ferric salt. The mode of preparation is not given. The only advantage claimed for it is the certainty of its speedy and complete absorption. [The charge of inutility, which holds good against the official arseniate, lies equally against the soluble compound. Arseniate of iron is only arsenic under another name; the proportion of iron in the compound being too small, as compared with that of the more active element, to produce any appreciable effect. If the combined operation of iron and arsenic be wanted, nothing is easier than to prescribe an adequate dose, say of the perchloride, together with the liquor arsenici hydrochloricus of the Ph.B.—*Rep.*] E. COLD-POWDERS.

(To the Editor of the LONDON MEDICAL RECORD.)

SIR,—The 'cold-powder' mentioned in your last, p. 102, is, no doubt, an efficacious preventive of cold, or it would not have had so good and so sustained a character for the last six years.

My object in writing is to warn non-medical readers against giving this powder to young children.

It is in fact a strong opiate, one grain in eight, and many children, although they may like the powder, would fare badly, I fear, if they were given even the minimum dose, three grains. Even for an adult, one or two grains of opium is rather a strong remedy to stop a cold. Perhaps better let the ills we have alone, than get into the habit every time the nose begins to run of taking a large dose of opium. I remember that many years ago an inquest was held at Ipswich, in which the medical men swore that they believed the death of an infant was owing to eight drops of syrup of poppies, and a verdict was given accordingly. But there is another danger in the too frequent habit of taking these powders,—I mean that of opium-eating, the most demoralising and degrading of all habits.

C. R. BREE, M.D.

Colchester, February 23, 1875.

A GRANT of 50*l.* has been made from the Worts Travelling Scholars' Fund (Cambridge) to Arthur Marshall, B.A., of St. John's, to enable him to visit Naples for the purpose of using Dr. Dohrn's zoological station and making researches in natural history, with the understanding that he sends specimens to the University, accompanied by reports.

MISCELLANY.

PROFESSOR VON LEYDIG, of Tübingen, has been nominated Professor of Comparative Anatomy in the University of Bonn.

DR. KIRCHHOFF, the newly appointed Professor of Physics in Berlin, will commence his lectures at the beginning of the summer session. The University of Berlin now possesses a rare combination of men eminent in physical science—Dove, Helmholtz, and Kirchhoff.

MR. SAMUEL WILSON, of Ercildoune, who recently gave £1,000. to the Acclimatisation Society of Melbourne, has sent 30,000. to the Chancellor of Melbourne University, intended for the erection of a hall, but free of conditions, and to be otherwise applied if the authorities think fit.

CREMATION.—The Municipal Council of Paris decided in August last that the necessary measures should be taken to open a competition with the object of ascertaining the best practical process of cremation or any other system leading to an analogous result. The Prefect of the Seine has, therefore, nominated a commission to fix the conditions and the programme of the competition.

PRACTICE OF MEDICINE BY WOMEN.—A motion was brought forward in the Belgian Chamber of Deputies on Friday the 19th ult. to allow women, provided with the necessary diplomas, to practise medicine in Belgium. Dr. Vleminckx opposed the motion. The Minister of the Interior said that he could give no opinion on the subject at present.

A NIGHT MEDICAL SERVICE IN MILAN.—The *Annali Universali di Medicina e Chirurgia* for January, says that the want, as yet unsatisfied in Milan, of a regular night medical service, has led some of the leading practitioners of the city to form a private association, under the presidency of Dr. Cesare Fumigalli, in order to make provision for the supply of the want referred to. A house has been taken for the purpose, and is to remain open daily from 11 P.M. to 7 A.M., commencing on February 8.

THE HEALTH OF THE ARMY.—A table published in the *Army Medical Department Reports* for 1872, shows that service in the army—or at all events in the United Kingdom—is by no means an unhealthy occupation, or one very destructive to life. The average annual death-rate per 1,000 for ten years was: in the Household Cavalry, 8.15; in the Dragoon Guards and Dragoons, 7.07; in the Royal Artillery, 8.33; in the Royal Engineers, 6.56; in the Foot Guards, 7.84; in the Infantry Regiments, 7.78; the highest death-rate occurring in the dépôts, where it was 10.92.

THE *Kölnische Zeitung* of February 10 gives an account of the researches of Professor Böhm of Dorpat on revival after cases of poisoning. He succeeded in reviving cats which had been poisoned by injection of potash salts into their veins, after forty minutes' duration of a state which was in no way different from actual death, the action of the heart and respiration having completely ceased. He obtained these results by artificial respiration and simultaneous compression of the breast in the vicinity of the heart. The professor points out the importance of the latter point, which he deems as essential as the action of the lungs. In any case, his researches are of high interest for the relation they bear upon the revival of poisoned persons.

THE INFLUENCE OF OCCUPATION ON LONGEVITY.—The opinions of country medical men all over the State of Massachusetts have, during the past year, been obtained by the board of health of that state with a view to determine the effect of occupation on longevity. It appears that a table collated for twenty-eight years shows the average age of farmers at death to be 65.13 years—figures far in advance of any other callings, and greatly exceeding

the lifetime of active mechanics, not in shops, who, averaging 52.62 years, appear next on the list. The opinions of the physicians consulted also show that the farmer's chances of long life are somewhat greater than those of any other class.

THE ATMOSPHERE OF THEATRES.—It would seem that the wealthy classes, who habitually frequent the stalls of the theatres, not only enjoy greater ease and facilities of hearing and seeing, but also occupy the most healthy situation possible under the conditions of a heated theatre containing a large number of persons. Carbonic acid gas, which is largely generated under these circumstances, behaves itself conformably to the law that the various elastic fluids, whether simple or compound, but without interchangeable chemical action, diffuse themselves uniformly throughout the extent of a limited space, independently of their respective density. Already in 1842, Le Blanc having analysed the air of the Opéra Comique at Paris, after a performance at which about a thousand spectators had been present, found 4.3 per 1,000 of carbonic acid in the highest regions of the theatre, and 2.3 per 1,000 in the air collected at the level of the pit, which established an almost double proportion in the upper regions. Orfila, in analogous conditions, found that out of ninety-five parts of air in a confined space there were 2.50 of carbonic acid above and 2.52 below, an almost equal division. Finally Lassaigne, in 1846, studying the distribution of carbonic acid in the strata of a confined atmosphere, after a lecture of one hour's duration in his amphitheatre, found the air to be composed as follows, the room being about twelve and a-half feet high.

	At Ceiling.	At Level of Floor.
Oxygen	19.80	20.10
Nitrogen	79.50	79.85
Carbonic acid	0.62	0.35

The proportion of carbonic acid in a confined space would therefore be somewhat higher in the highest zones than in the lower regions.

AN IMPORTANT SANITARY IMPROVEMENT.—Of late years, the invention of Reflectors has taken a strong hold on the English public, who seem to, at last, realise the vital importance of living in a pure atmosphere. Thousands of Daylight Reflectors have been and are continually manufactured by Mr. Chappuis, the Patentee, of 69 Fleet Street, London. By consulting him, you will learn the means of dispensing with gas in daytime, and of saving your money and your health.—[ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

WEDNESDAY, MARCH 10, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON CATARRH OF THE SMALL INTESTINE IN CHILDREN. BY DR. ALOIS MONTI, OF VIENNA.*

(Concluded from page 126.)

In regulating the diet of artificially fed children, I observe the following principles.

Where badness of cow's milk is the cause of catarrh of the small intestine, I give the milk diluted with fatted veal-broth, in the following proportions: To children under three weeks old, one part of milk and two of broth; to children between one and two months old, equal parts of milk and veal-broth; between two and three months, two parts of milk and one of broth; and to children four months old and upwards, three parts of milk and one of broth. Only in the case of children above one year old is the milk entirely withdrawn for a few days, and soup substituted for it.

In many cases I have made the experiment of substituting, for notoriously bad cow's milk, condensed milk at a corresponding degree of dilution. In many cases it has done good service; but I have often been again obliged to have recourse to other substitutes. In the use of condensed milk, it is of great importance to select the proper degree of dilution with water. According to my experience, the following quantities of water should be added to one part of condensed milk; for newly born children, fifteen parts; for children from two to four weeks old, fourteen parts; from one to three months, thirteen parts; from three to five months, twelve parts; from five to ten months, ten parts.

In cases where excessive dilution of fresh cow's milk was the cause of the intestinal catarrh, this was indicated by dyspepsia, and a suitable degree of dilution was ordered. When the disease arose from the improper use of various admixtures to cow's milk (such as fennel-water or rice-water) these were laid aside. When the improper administration of amylaceous food appeared to be the cause of the malady, it was stopped, and a diet suitable to the child's age was given.

In the cases of older children (from eight or nine months to two years old) attacked with chronic intestinal catarrh, I have withdrawn milk from the diet for some days; and if improvement did not then take place, I have used raw milk, warm from the cow, either exclusively or along with raw meat. I am convinced of the successful results of the warm milk, and can strongly recommend it. In using it I begin with a pint of milk daily, and cause mucilaginous soup and raw meat to be given with

it. If it be well borne, I gradually increase the quantity to a quart daily. With this dose I have repeatedly seen children who had become emaciated almost to skeletons not only cured of their intestinal catarrh in eight or ten days, but also increased in weight by one pound. It is to me incomprehensible how there can be any question of the unconditional withdrawal of milk, since, under the use of warm (*kuhwarm*) milk in cases of chronic catarrh of the small intestines in children from nine months to two years old, I have very often seen the most astounding and brilliant results.

In cases where neither veal-broth with milk, nor properly diluted condensed milk, or warm cow's milk produced improvement, I have always advised that the use of artificial food should be desisted from, and that the child should be given breast-milk. Unfortunately, however, this has not always been possible, and therefore I have made experiments with the various substitutes for milk.

Liebig's soup and its substitutes, such as Löflund's children's food, have in many cases afforded me good results; but I am far from praising them as specifics against intestinal catarrh. Liebig's soup was given undiluted, and the exclusive use of it in children above five months old was in very many cases followed by happy results. Equally good service was rendered by Nestlé's children's meal. It is, however, important to remember that, especially for very young children, its use is not always wely borne.

In cases of chronic catarrh of the small intestine, raw meat was given either simultaneously with cow's milk or in combination with soup. In older children it frequently afforded happy results; and in place of it the juice of meat was given with good effect to small sucking infants.

In cases of chronic catarrh of the small intestine from the use of bad milk, I have many times used cocoa and acorn-coffee, and I have ordered the latter especially for scrofulous and rickety children. For children under one year of age, it is prepared in the same way as ordinary coffee; and, according to the child's age, is either given with an equal quantity of milk, or in the proportion of two or three parts of milk to one of acorn-coffee.

Of cocoa I have, as a rule, used the powder of the beans deprived of their husks; the latter I have used only in some special cases. The cocoa is prepared in the same way as acorn-coffee. For children under one year of age, the cocoa or acorn-coffee is boiled in pure milk. In children under three months, I rarely saw a favourable result; and I must therefore warn against feeding such children exclusively with cocoa or acorn-coffee, as some are accustomed to do. In cases of chronic intestinal catarrh in older children, I give the cocoa or acorn-coffee twice or at most thrice a day; and this mode of administration in combination with other articles of diet, such as Nestlé's food, soup, raw meat, etc., has often done good service. If the cocoa and acorn-coffee be badly borne and pass away undigested with the stools, it is better to abstain from their use.

From what has been said, it is plain that the choice of the diet depends on the individuality of the child, and that, when the intestinal catarrh does not become better under the use of one dietetic method, recourse should be had to another which is perhaps more suited to the age of the child, and most nearly approaches human milk.

Wine was frequently given to children between

* From the author's 'Pædiatric Contributions,' about to be published. *Wiener Medizinische Wochenschrift*, nos. 1 et seq., 1875.

eight months and two years old, suffering from chronic catarrh of the small intestine; red wine containing tannin being preferred. The quantity given was one to two tablespoonfuls daily, according to the strength of the wine.

Baths were ordered in acute intestinal catarrh if collapse set in rapidly. Lukewarm bran-baths were chiefly given, once or twice daily. In cases of chronic intestinal catarrh with dry skin, baths of this kind were given with the view of aiding the change of substance and the circulation. In anæmic children, artificial Franzensbad moor-baths, or baths of rock or sea-salt, often produce successful results.

The medicinal treatment was directed to the symptoms.

In simple acute catarrh of the small intestines, nothing but opium and its preparations, such as the tincture and Dover's powder, were given in a number of cases, both to infants at the breast and to older children. In my experience, the following are the doses of opium suitable, according to the age. For children from birth up to the age of three or six weeks, according to their development, I order one drop of simple tincture of opium in three ounces of distilled water or of mucilage; of this, a teaspoonful is taken every two or three hours. As newly born children are sometimes very susceptible to the influence of opium, it is advisable to warn the parents not to give it during the hours of sleeping. For children from seven to eight months old I order in each two ounces of water or gum mixture, one drop; from eight to fifteen months, two drops; and at the age of two years, according to the degree of development, from two to three drops.

I have, however, avoided the use of this medicine in prematurely born children, in very anæmic and reduced children, in those presenting cerebral symptoms, and in those in whom there was a high degree of hydrocephalus; also in bronchitis, pneumonia, and other affections of the respiratory mucous membrane. Under such circumstances, children readily show symptoms of poisoning.

The susceptibility of children to opium is very variable; for, while in some the smallest doses give rise to symptoms of poisoning, in others opium produces but little effect of this kind, and is tolerated in comparatively large doses. I remember a case of a child two years old, to whom I gave daily two drops of tincture of opium, increasing the quantity to eight drops, without observing the least indication of toxic symptoms. It is my custom always to begin with the small doses of opium above mentioned, and, when it is evident that it produces no toxic effect, I increase the dose; always warning the parents to omit the medicine if the sleep become of longer duration and deeper than usual. Besides tincture of opium, I use Dover's powder in the following quantities: for children under three months, one grain daily in from eight to twelve doses; for children from three months to one year old, one grain in six doses; for children two years old, two grains in six doses.

If the intestinal catarrh be accompanied by symptoms of dyspepsia, and the vomited matters and stools be strongly acid, I combine an alkali with the opium, often, for example, in the following formulæ.

R. Pulveris Doveri gr. j; pulveris oculor. cancrorum gr. xx; sacchari albi 3ss. Divide in partes viij. One of the powders to be taken every two hours.

R. Sodæ bicarbonatis gr. vj; aquæ fontis 3ij; tincturæ opii simplicis gtt. j; syrapi simplicis 3ij. One teaspoonful to be taken every two hours.

When there is no vomiting, but the stools contain undigested casein, I have frequently employed the Paulinia sorbilis and trisnitate of bismuth with successful results. The following are the formulæ which I use.

R. Pauliniæ sorbilis gr. viij; pulveris Doveri gr. j; sacchari albi 3ss. Misce, et divide in partes vj. One powder to be taken every two hours.

Or, R. Bismuthi trisnitratis gr. iij; pulveris Doveri gr. j; sacchari albi 3ss. Misce, et divide in partes vj. One to be taken every two hours.

In cases of intestinal catarrh, without symptoms of dyspepsia, astringents are given with opium, in some such formula as the following.

R. Tincturæ ratanhiæ gtt. xx; tincturæ opii simplicis gtt. j; aquæ fontis 3ij; syrapi simplicis 3ij. A teaspoonful to be taken every two hours.

Or, R. Tannini puri gr. iij; pulveris Doveri gr. j; sacchari albi 3ss. Misce, et divide in partes vj. One powder to be taken every two hours.

When catarrh of the small intestines has been complicated with acute gastric catarrh, attended with vomiting, I have given an acid in combination with opium, or even a small dose of rhubarb.

R. Acidi muriatici diluti Mij — iij; aquæ fontis destillatæ 3ij; tincturæ opii simplicis gtt. j; syrapi simplicis 3ij. One teaspoonful to be taken every two or three hours.

Or, R. Pulveris radices rhei Chinensis, pulveris Doveri, aa gr. j; sacchari albi 3ss. Misce, et divide in partes vj. One powder every two hours.

In cases of acute or chronic catarrh of the small intestines, accompanied with chronic gastric catarrh, loss of appetite, eructations, hiccough, coated tongue, and an offensive smell from the mouth, sulphate of zinc, calumba, and roasted rhubarb were used—the last especially when the stools were colourless. For instance, in the case of children under one year of age, the prescriptions were—

R. Sulphatis zinci gr. j; aquæ fontis destillatæ 3ij; tincturæ opii simplicis gtt. j; syrapi simplicis 3ij. One teaspoonful four or five times daily.

R. Pulveris radices rhei tostæ gr. ij — iv; pulveris Doveri gr. j; sacchari albi 3ss. Misce, et divide in partes vj. From four to six powders to be taken daily.

R. Decocti radices calumbæ 3ij; tincturæ opii simplicis gtt. ij; syrapi simplicis 3ss. One teaspoonful every two hours.

When intestinal catarrh was complicated with mild bronchial catarrh, infusion of ipecacuanha was given with a small dose of opium.

In cases of chronic intestinal catarrh, I abstain from prescribing many medicines, whether mere astringents, or such remedies as calomel, nitrate of silver, logwood, etc., because I am convinced from experience that not much good is obtained by their use. In anæmic children, however, I have frequently observed astonishing results from the use of small doses of iron; but I must warn against too large doses of this medicine. For children under one year, the following were the most usual prescriptions.

R. Ferri carbonatis saccharati, pulveris Doveri, aa gr. j; sacchari albi 3ss. Misce, et divide in partes vj. From two to four powders to be taken daily.

R. Ferri oxidi dialysati gtt. x; aquæ fontis 3ij; aquæ menthæ, syrapi simplicis, aa 3j. From four to six teaspoonfuls to be taken in the course of the day.

R. Liquoris ferri sesquichloridi gtt. vj; misturæ gummosæ 3ij; syrapi corticis aurantii 3vj. Three or four tablespoonfuls to be taken in the day.

I have not used enemata in catarrh of the small intestine. To relieve the colicky pains and moderate the

peristaltic movements, Priessnitz's fomentations are useful in acute cases; in chronic cases, with much meteorism, cold compresses were applied to the abdomen and frequently renewed.

A. HENRY, M.D.

GUBLER ON CINESIALGIA, ESPECIALLY IN MYODIASTASIS, AND ITS IMMEDIATE CURE BY LOCALISED FARADISATION.

M. A. Gubler (*Journal de Thérapeutique*, 1874, pp. 697-898), has written a long memoir on certain painful affections of the muscles, which, according to him, have hitherto been confounded with myosalgia of inflammatory character and neuralgia, but which, by the mechanism of their production, and their subjective or apparent peculiarities, as well as by their course, termination, and the therapeutic agents to which they yield, must be distinguished from all other painful affections of the sensory-motor system. Cinesialgia, or kinesialgia, means, according to him, that state of the muscle in which its contractility cannot come into play without producing locally a keen and sometimes intolerable pain, which is always more or less incompatible with the regular exercise of the motor function. Kinesialgia is therefore not identical with myalgia, which latter means only the pain of muscular rheumatism. It occurs wherever contractile tissue exists, in striped as well as in unstriped muscles, whether animated by cerebro-spinal or by sympathetic nerves.

The conditions which give rise to this symptom are chiefly of a two-fold character, viz., inflammatory and non-inflammatory. Muscular contractions are painful in rheumatism (myalgia, lumbago), sometimes merely in consequence of a chill without rheumatic diathesis, and myositis in general; likewise after contusions, ruptures, and consecutive injuries, or when the fleshy parts are the seat of a break of continuity from so-called spontaneous ulceration. The pain of pleurisy is only kinesialgia, restricted to a small space. Tenesmus, the forcing pain of dysentery, dysuria and vesical spasm from cystitis, cramps in the stomach from simple ulcer of the organ, and other allied affections, may be put down to inflammation; but there are other kinds of pain where no inflammation exists, as, for instance, in pleurodynia, cramp in the calf, and certain forms of tic, etc. The most frequent examples of non-inflammatory kinesialgia, however, arise from a muscular effort or a false movement; and for this state M. Gubler has coined a new word, viz. myodiastasis or muscular diastasis. The Greek word *διάσπασις* signifies separation, and would therefore at first sight appear to be very suitable for signifying a violent divulsion of two articular surfaces, but less so to muscular efforts. The word *διάτρεσις*, on the contrary, expresses tension or distension of the parts, so that the word 'myodiastasis' floated before the mind of M. Gubler as most appropriate for the condition under consideration. But, as he discovered in Castelli's lexicon, that the word diastasis had already been previously used to signify distension, he ultimately resolved to adopt this latter as more euphonic; besides which it had, in his eyes, the additional advantage of being somewhat vague, and therefore corresponding better to the complexity and relative obscurity of the pathological facts.

This traumatic form of kinesialgia is generally owing to an excessive or irregular contraction, resulting from an intentional or instinctive effort; but it

may also come on after a very moderate movement. It is produced by a distension of the muscular fibres, which may proceed to partial rupture, and becomes the evident sign of a kind of muscular sprain, which appears to be favoured by incohesion of the fleshy substance in the state of relaxation. This causes want of synergy in the different portions of the same muscle, or several allied muscles.

Its symptoms are the pain of contraction, and the functional disturbance caused by it. From this it follows that the chief seat of the affection will be where there is much muscular work going on. Thus, for instance, the work of the dorsal muscles is already considerable, simply for maintaining the erect position; but if a heavy weight be added to this, it becomes enormous; and the long muscles of the back and the lumbo-sacral region are therefore principally liable to become the seat of myodiastasis. Out of twenty-six cases which M. Gubler has observed, fourteen were cases of lumbar myodiastasis. After this, it is chiefly the neck and upper portion of the back which suffer, and the ankle-joint.

The fact that this sprain is not very frequently observed, considering the immense number of opportunities for its production, and that it is often noticed amongst people who lead sedentary lives, whenever they have by accident done some muscular work, led M. Gubler to the opinion that it is not only owing to intensity of contraction, but that it also depends upon the manner in which this is effected, and the anatomical conditions of the muscular mass. Thus, myodiastasis has been known to come on on getting out of bed; after sneezing; in ataxy; in sudden movements excited by fright or determined by any kind of reflex actions; that is to say, 'where the surprised system has not the time given it to prepare its means or to regularise its efforts'; and in the rheumatic diathesis. In the latter case, the slightest movement is sometimes sufficient to bring on kinesialgia; while, when the muscular system is in its normal condition, violence is necessary for producing it.

The symptoms of myodiastasis are, first, an acute pain on motion, which is often severe enough to make the patient scream; this is constant, and, as a rule, there is neither pain nor tenderness during repose. In some persons, however, a feeling of malaise and dull pain are felt even when at rest. Sleeplessness is often present, and œdema of the parts may follow the first occurrence of the diastasis. When this is observed, the distension of the muscular fibres has probably been so severe as to cause actual rupture. There are, however, no inflammatory symptoms, such as heat or redness on increased sensibility, which is not surprising if we consider how apathetic muscular substance usually is. Indeed, myositis often remains latent; muscular abscesses are only revealed on the *post mortem* table, and foreign bodies remain in the muscles without exciting inflammatory action. The pain of contraction suffices, however, without there being any vascular complication, to impair or even to suppress the motor functions, not only in the affected part, but also beyond it. In fact, diastasis of a single muscle is capable of immobilising a limb or even the whole body, owing to the solidarity of the different parts of the system in the mechanism of effort. Nobody is surprised to find that it should be difficult to hold up the head when the muscles of the neck have been sprained, or that walking should be troublesome when one has a traumatic lumbago;

but it appears singular, at first sight, that movements of the forearm should cause pain in the neck, or that elevation of the arm should send a shoot of pain into the loins and even the pelvis. On this account the patients either will not move at all, or they manœuvre most ingeniously so as to put into play only the smallest possible number of sets of muscles, and to localise contraction.

These symptoms render the diagnosis easy in the majority of cases. Only where the occasional cause is not very manifest, for instance, when the effort takes place during a deep sleep, or where the patient is subject to the rheumatic diathesis, a doubt may sometimes arise. However, in such hybrid cases the uncertainty of diagnosis will fortunately be without influence upon the choice of remedies, as the same means of treatment will cure muscular rheumatism as well as kinesialgia. There are other morbid conditions in which every movement gives rise to a pain which has nothing in common with kinesialgia, such as sprain of the joints, osteitis, chondritis, synovitis articularis and tendinosa, phlegmasia of serous membranes, or of nerves in the neighbourhood of joints, fractures, rupture of tendons, and fibrous parts in general, foreign bodies lodged in the tissues, calculi impacted in excretory organs and their ducts. But in all such cases the seat of pain is outside the muscles, in the inflamed organs, and there are always other symptoms foreign to diastasis which will render the diagnosis tolerably easy.

The duration of the kinesialgia varies a good deal according to the degree, extent, and seat of the anatomical lesion, and likewise according to individual conditions, such as repetition of movements, rheumatic diathesis, dwelling in a damp and cold place, etc. It sometimes lasts only a day, in other cases a week, and even as much as two months. Gradually the pain becomes dull instead of acute, and a simple feeling of malaise may thus remain for a time. The structural change mostly disappears at the same time with the morbid sensation; in some rare cases, however, there is a tendency to repetition of these muscular sprains, and in one case M. Gubler has seen sciatica come on after it.

The means generally recommended for the treatment of diastasis, such as rubbing, shampooing, hot fomentations, baths, etc., are generally only palliative, and faradisation is not only the most effective but also the quickest treatment. The primary current is generally preferable to the secondary, on account of its being less painful and possessing less tension. As a rule moistened conductors are used, and faradisation of the skin by the wire-brush is only required when the diastasis is complicated with neuralgia.

M. Gubler appears as a rule to have used a very powerful current, for he says that the pain produced by it was in the majority of cases so severe as to make even the bravest patients scream; one asked for mercy during the sitting, and another fainted under the influence of it. It seems to us, therefore, preferable, either to prolong the application and to use a more feeble faradic current, or to employ the continuous current instead, which is far more pleasant than, and equally effective with, faradisation. M. Gubler excuses the application of a powerful current by saying that, if the sitting be short and feeble, the effect produced is not so striking; and no doubt this is quite correct, as far as faradisation is concerned. In many cases one application has been sufficient, but in others two, three, or even five

sittings have been found necessary. 'Success is generally so prompt that at first the patients refuse to believe in a cure, and retain their pitiable attitude and timid expression. But when the individual, emboldened by our assurance, ventured on a few movements which were only just before prohibited by cruel sufferings, the scene was truly comical; the face of the patient offered a curious mixture of stupefaction and joy; and one often saw him, with astonished looks, a smile on his lips, carry out a crazy gesture, as if to prove to himself that he had really recovered the full liberty of his movements.'

A pathogenic theory of myodiastasis has up to the present time no basis in pathological anatomy, and must, therefore, as yet only be founded on more or less reasonable conjectures. Such appear to be 1, stretching and contusion of nervous fibres; 2, rupture of fibrous tissues; 3, dislocation, twitching, and attrition of the muscles; 4, distension and rupture of contractile fibres.

The first of these suppositions would appear to be untenable; for, if there were a nervous lesion, the pain would not completely disappear in the intervals of rest, and come on again only just at the moment of contraction; there might be paroxysms, but still the pain would be continuous, and the attacks would not only be excited by the displacement of the parts.

The second conjecture, of rupture of fibrous tissues, is not any more acceptable, because the force that is required for tearing a tendon or an aponeurosis is so enormous that it cannot be admitted for such cases, since in many of them the muscular effort has only been slight. With regard to the third, viz., dislocation of muscular fibres, it appears not impossible, but hardly probable. In certain thick muscular bundles, such as the gastrocnemius, deltoid, and gluteus, we can easily conceive the gliding of a bundle which forgets to contract, between two bundles which have become rigid by an energetic contraction, and which expel it as a cherry-stone pressed between two fingers would be; the passive bundle, which would be compressed by the active portions of the muscle, might suffer a kind of contusion or bruise, which would be accompanied and followed by pain.

Still all this is only speculation; moreover, the mechanism of a partial dislocation is difficult to understand in homogeneous muscles with parallel fibres; and the idea of attrition and smashing of muscular fibre does not accord with the promptitude and constancy of the therapeutical results.

The only really satisfactory hypothesis therefore appears to be, to assume distension of muscles with or without rupture of some contractile fibres. The great ease with which muscular bundles may, under certain circumstances, become distended or torn, is caused by a special modification of the contractile substance which has hitherto escaped the attention of pathologists. The conditions of repose or activity of the muscular fibre cause peculiar variations in its molecular state and physical qualities, such as elasticity, extensibility, and cohesion. Dead muscle resists traction so little, that its force of cohesion is overcome by a few pounds' weight only. The cohesion of muscular fibres during life, even in the state of relaxation, is no doubt greater; nevertheless, there is a vast difference between the tenacity of muscles hardened by contraction and in the flaccid state. In view of this fact, the explanation of muscular sprain does not present any difficulty; for it suffices that a muscle or portion of muscle should be in the state of relaxation and relative incohesion, in

order to allow distension or tearing by a feeble traction. This condition is frequently brought about from a want of synchronic action between synergic muscles and the different portions of the same muscle. This want of harmony causes occasionally myodiastasis at the moment of awaking, or when movements are produced by reflex action, under the influence of fright, or when occasioned by a peripheral excitation, as in sneezing. Why does a muscle not act in unison with its synergics? Why does a portion of a muscle remain inert when the rest enters into contraction? No doubt because the tardy muscle or bundle responds badly to stimulation, or because the nervous discharge arrives at it too late or with too little intensity. If a muscle be at all large, its different portions are not animated by the same motor nerve-fibre, and may therefore be considered as so many distinct and autonomous muscles. This view is quite accepted for the digastric and the straight muscles of the abdomen; but it seems also rational if applied to other muscles, especially if we consider that in many muscles the bundles are intersected by partial fibrous formations which render them really polygastric. These partial intersections have not sufficiently attracted the attention of anatomists. They are found in the gemelli, the rectus femoris, the glutæi, sartorius, and many others. This anatomical arrangement, joined to the presence of a distinct nervous branch in each muscular segment, assures to the different portions of a muscle a reciprocal independence, which allows us to consider them as entire muscles. When, therefore, in a muscle which is divided into two halves by a fibrous line, one of the ends contracts while the other remains inert, this latter will undergo a stretching which will surpass the limits of its elasticity and produce distension.

JULIUS ALTHAUS, M.D.

JENNER ON THE ETIOLOGY OF TYPHOID FEVER.

Sir Wm. Jenner's presidential address to the Clinical Society (*Lancet* and *British Medical Journal*, Feb. 20) is so full of valuable observations and practical suggestions, that it is almost impossible to make a satisfactory abstract of it. We content ourselves therefore with giving an abridgment of what is perhaps the most interesting part, viz., his remarks on the etiology of typhoid fever.

It is said by some that typhoid fever is undoubtedly contagious, and that, being contagious, it can never originate *de novo*; that is to say, as it can be proved in some cases to have its origin in the entrance of the emanations of the sick into the previously supposed healthy body, it can never arise in any other way. On the other side, while admitting that the disease may be spread by the emanations from those suffering from it, it is said that any admixture of sewage (decomposing animal excreta) with fluids used for drinking purposes, although no typhoid excreta are present, will produce typhoid fever *de novo*.

One general assumption made by those who advocate the sole origin of typhoid fever by contagion requires special consideration. It is this, that no admittedly contagious disease ever originates in any other way than by contact with the emanations from the sick, and therefore that typhoid fever, which spreads, as is generally admitted, by contagion, can

be spread in no other way. Sir William Jenner says that his own prejudices are strongly in favour of the specific origin of this in common with all contagious diseases, but he thinks that the weight of evidence and of argument are rather on the other side. Of small-pox, for example, the most contagious of these diseases, we may fairly conclude that it never originates *de novo*. Sir William Jenner does not hesitate to say, notwithstanding Dr. W. Budd's assertion to the contrary, that it is rare that an isolated case of small-pox cannot, with due care, be traced to its probable source, and when a case has been imported into a locality previously free from the disease, new cases almost invariably spring up in its vicinity; so that the contagious origin is proved first by tracing the case to its source, and secondly from the new cases which spring up from the first isolated one.

But when we pass to the other end of this class of diseases, we find an unexpected difficulty in maintaining this theory of specific contagion. Diphtheria and erysipelas of the head and face are both undoubtedly contagious diseases, though much less contagious than small-pox; it is more common for the healthy who are exposed to the emanations from the sick to escape these diseases than to escape small-pox under the same circumstances. Now we should expect that the more contagious a disease—that is, the less the quantity of the poison needed, the shorter the time of exposure to the poison necessary, and the less preparation required in the system of the person receiving the poison—the more difficulty we should have in tracing it back to its primary source; whilst with the diseases of this class which are the least contagious,—which require for their spread a longer exposure or more decided dose of the poison, or the administration of the poison in a particular way by a special channel—we should expect that we should more easily be able to trace every new case to its origin, that is, if every new case be really due to exposure to the emanations from the sick of the same disease. But this *à priori* reasoning does not agree with our experience; for, while in regard to small-pox it is the exception not to be able to trace the source of the contagion, in regard to diphtheria and erysipelas of the head and face it is exceptional that the first case can be traced back to contagion. Typhoid fever, like diphtheria and erysipelas, holds a low position as regards its contagious quality; the poison must be in large doses, or long breathed, or must be taken into the stomach in order to propagate the disease; therefore it ought to be possible, in the majority of cases, especially in country places and isolated houses, to trace this disease also to its source, if the source be in every case the excreta or emanations of those suffering from the disease. But, in fact, in a very large proportion of the solitary cases observed it has not been possible thus to trace its origin; and not only so, but there are a sufficient number of cases recorded to make it probable that the admixture of sewage, not typhoid, with drinking-water may produce the disease *de novo*, and most medical practitioners have met with cases in which the breathing of greatly diluted sewer-gas continuously for some time, especially at night, has also seemed to be able to produce typhoid fever *de novo*.

With reference to these three contagious diseases which cannot in many cases be traced to pre-existing cases of the same disease, there are three points worthy of notice. First, they are more liable than

the most contagious, as small-pox, measles, and scarlet fever, to recur in the same individual. Secondly, when not referable to contagion, each is pretty constantly referred to one particular cause—diphtheria to exposure to cold; erysipelas to exposure to cold when the individual was depressed from fatigue, mental or moral causes, fasting, etc.; and typhoid fever to foul gaseous emanations or to contaminated water. Thirdly, certain primary constitutions seem more prone than others to suffer from these less contagious diseases; whilst all people seem to be susceptible when exposed to the poison of scarlet fever, of measles, or of small-pox, the other three diseases occur especially in certain constitutions. Diphtheria, for example, comparatively a rare disease, will occur in several members of the same family at long intervals of time and in localities widely separated, thus showing a great constitutional proclivity to the disease.

In concluding this portion of his address, Sir William Jenner said, 'I do not say, nor do I think, that the arguments and facts which can be adduced in favour of the origin *de novo* of any of the contagious diseases are conclusive; but I do say, and maintain, that they are strong enough to make us pause before we accept the theory advocated by Dr. William Budd, and to which Professor Tyndall has lent the weight of his great name, a weight, however, which would be greater on the point in question if he had himself studied the subject on which he has, I am sorry to say, addressed the public in a strain calculated to check unprejudiced individual inquiry. To my mind the question must be held to be still *sub judice*: new facts, sceptically scrutinised and carefully recorded, are required to settle it. It is only in exceptional instances that cases free from all possible, or at least from all probable, sources of error, can come under notice. Such cases can only be seen in private practice, and especially in country practice; and it is for this reason that I dwell particularly on this subject to-night, my desire being to urge the careful observation and reporting of these isolated cases.'

J. W. LANGMORE, M.D.

PATHOLOGY.

GONZALES ON CYSTICERCUS IN THE BRAIN IN A CASE OF PROGRESSIVE PARALYSIS OF THE INSANE.—The *Gazzetta Medica Italiana-Lombardia* for January 16 contains a paper read before the Psychiatric Society in Milan, by Dr. E. Gonzales, resident medical officer of the Lunatic Asylum in that city, on a case in which cysticerci were found in the brain of a patient who had died of progressive paralysis.

The patient, D. A., aged forty-one, was admitted into the General Hospital of Milan on March 10, 1871, suffering from symptoms which led to the diagnosis of general paralysis of the insane. In August, his condition being unimproved, he was removed by his wife, but was again admitted in October, and in March, 1872, was transferred to the Asylum, where the diagnosis was confirmed. On June 17, he died of syncope consecutive on an epileptic fit.

In 1863, having previously enjoyed good health, he had a sudden attack of epilepsy. The attacks at first recurred at long intervals, and were sometimes followed by sopor, sometimes by fits of mania.

From being mild and affectionate, he became violent and irascible, and negligent of his duties. His intellect, at first clear, became confused; the epileptic attacks became more frequent, and he fell into a state of general emaciation, with stuttering and uncertainty of gait. He had an idea that he was the possessor of great wealth, and that, though of known honesty, he was accused of petty thefts. His wife, to whom he was formerly much attached, he regarded as the cause of his disgrace. He was subject to hallucinations of vision and to insomnia. He was treated by nitrate of silver and other remedies, both in the General Hospital and in the Asylum, but without any improvement of his condition.

At the necropsy, which was made thirty-six hours after death, the dura mater was found to be somewhat thickened and firmly adherent to the cranium; the pia mater was congested. The cerebral convolutions were dense, and pressed against each other; the anterior cases were much flattened, as if atrophied. Half of the convex surface of both hemispheres was occupied by ten more or less transparent cysts of various size and shape, most, however, being round, and of semi-solid consistence. They were of a pale yellow colour, and were partly adherent to the pia mater and partly embedded in the cerebral substance, from which they were removed by enucleation. The lateral ventricles were distended with serum; the right contained seven cysts attached to the ependyma, and in the left was a cyst floating free in the fluid. In the left Sylvian fissure there were five cysts, joined together in a cluster. Resting on the medulla oblongata, between the foramen cæcum and the point of decussation of the pyramids, was another cyst; on removal, it left no depression. The medulla oblongata was of firmer consistence than normal, and it was somewhat of a straw colour; the cerebellum was normal. The lungs were oedematous and hyperæmic; the heart was healthy. Nothing abnormal was found in the abdominal and pelvic viscera.

The cyst removed from the medulla was examined microscopically under the direction of Dr. Visconti; and the head of a cysticercus, furnished with a double row of hooks and four lateral suckers, was distinctly seen. The medulla oblongata presented alterations which were also found in five other cases of general paralysis. The nerve-cells were changed in form, and consisted of a homogenous bright substance, without any nucleus or nucleolus; the margins in some cases being well defined, in others imperfectly.

Dr. Gonzales remarks that his case is interesting on account of the rarity of free parasitic cysts in the cavities of the brain, and because hitherto there has been no recorded case of cysticercus located on the medulla oblongata, nor of association of the parasite with progressive paralysis of the insane.

The author regards the progressive paralysis as not having been caused by the cysticerci, but by the pathological changes in the medulla oblongata.

MEDICINE.

FRÄNKEL ON A CASE OF MULTIPLE PARALYSES OF CRANIAL NERVES.—Dr. B. Fränkel, of the Augusta Hospital, Berlin, relates the following case in the *Berliner Klinische Wochenschrift*, January 18, 1875. The patient, a clerk, twenty years of age, had suffered from a discharge from his right nostril for several years, which he had observed was not so pervious as the left. In February last he experienced acute pains on the right side of the forehead, accompanied with attacks of a fainting character. About the end of April a tumour was observed at the right angle of the maxilla, and the patient, who had been slightly deaf from childhood, had entirely lost the sense of hearing on the right side. In this state he was admitted into the hospital, and was taken by Dr. Fränkel to the sitting of the Berlin Medical Society for inspection by the members.

On examining the mouth, it was observed that the right side of the tongue was atrophied and paralysed. The apex of the tongue was protruded towards the right side. If the patient made grimaces, it was seen that the muscles supplied by the facial nerve possessed their normal innervation. On looking further into the cavity of the mouth, it was seen that the uvula and soft palate were drawn to the left of the mesial line. This deviation was more distinct when the patient pronounced *a*. By a laryngoscopic examination the epiglottis was seen to be inclined backwards, with its right edge lower than the left. The right side of the larynx was covered with mucus; the right vocal cord, relaxed and curved, had the same appearance as is presented in a corpse. The right arytenoid cartilage was inclined forward, and in this state the parts remained immovable during both inspiration and expiration, and in phonation, so that the left vocal cord was seen to project over that of the right side during these acts. Here there was paralysis of the lingual, palatal, and laryngeal muscles. The movements of the hyoid bone and larynx in swallowing were normal. The position of the hyoid bone was horizontal. The upper angle of the thyroid cartilage was rather deeply turned to the left, but this may have been owing to a slight curve in the neck, which the patient had from infancy. The movements of the head were equally performed. The sensibility of the skin was equal on both sides, except in a circumscribed space of the right auditory passage. Reflex coughing could be excited in the left but not in the right meatus. The surface was sensitive at the tip of the tongue, the lips, and inside of the cheeks on the right side, but gradually diminished towards the root of the tongue, and was entirely wanting in the fauces on the right side. In laryngoscopic examination a sound could be passed down to the usually sensitive laryngeal surface, on the right side, without exciting reflex action. Mastication and deglutition were greatly impeded by the inability to control the position of the morsel on the right side, so that to avoid choking he was obliged always to keep the food to the left side of the mouth. Taste was also impaired in the parts insensitive to touch.

Dr. Fränkel considers that this case corroborates the ageusia, described by Hirschberg (*Berliner Klinische Wochenschrift*, 1868, no. 48), from paralysis of the trigeminus, and supplies a fresh proof that taste is the result of the distribution of the fifth

pair and chorda tympani to the anterior part of the tongue, and of the glossopharyngeal nerve to its posterior portion.

With reference to the senses, hearing, it has already been stated, was impaired; visual power was perfect; smell was slightly feeble on the right side, possibly from the narrowness of the nostril preventing free inspiration. Dr. Fränkel thus summarises the phenomena related: total paralysis of the right hypoglossus, of the right glossopharyngeal, and of the right vagus, as far as concerns the laryngeal superior and most probably the auricularis. As regards other branches of the vagus, there was no functional disorder of the lungs or of the abdominal viscera. The pulse was feeble, and averaged from 110 to 120 in the minute.

The interest of this case is further enhanced by the observation that there were indications of paralysis of the superior ganglion of the sympathetic. The left pupil had become smaller than the right. There was no strabismus, but a distinct exophthalmia of the right side. The temperature of the right external auditory passage was slightly above that of the left. The surface of the tympanum was depressed and injected. The mouth was constantly filled with saliva.

The cause of these multiple paralyses was doubtless the tumour already mentioned as existing under the angle of the superior maxilla, under and in front of the sterno-cleido-mastoid muscle. It was of a firm consistence, elastic and movable, of about the size of an apple; it extended into the pharynx, which it pressed forward, occupying also the nasal fossa. The point of a catheter passed into the nostril was turned upwards and inwards to the left ere it reached the back of the cavity. This tumour bled on the slightest touch, and had a red puffy mucous appearance.

W. B. KESTEVEN.

WEBB ON A REMARKABLE CASE OF ANEURISM OF THE AORTA.—Dr. W. H. Webb of Philadelphia gives the details of a case of aneurism of the arch of the aorta, which is chiefly remarkable on account of its long duration; the survival of the patient sixteen days after perforation of the chest-wall; and the size of the clot, which plugged the perforation, and protruded beyond the level of the skin.

The patient, a woman about forty-three years old, at the time of her death, had been under the observation of Dr. Da Costa for nearly eight years, suffering from aneurism of the arch of the aorta. The disease had probably commenced three years previously to her seeking advice, after a severe fright and sudden exertion; there was no other obvious cause of vascular disease to be discovered. Even when first examined, the patient presented bulging of the upper part of the sternum, and other marked signs and symptoms of thoracic aneurism. There was nothing specially remarkable about these.

During the first four years of the woman's attendance at the hospital, the gradual enlargement of the tumour was watched. In the course of the five years' attendance the skin over the sternum, where the tumour was pointing, became discoloured. During the sixth year the tumour was accidentally struck 'by a large scrubbing-brush, and diminished considerably in size.' A few months later, it increased once more in size, rather suddenly. During the next twelve months, there was no material change in the condition of the patient.

In January, 1874, after the patient had been more than seven years under treatment, the symptoms became alarming. At the most anterior portion of the sternal tumour there was a spot about three-quarters of an inch in diameter, covered by the merest film, which looked as if ulceration were taking place, and the current of blood could be felt beneath it. To this spot a plaster was applied, consisting of equal parts of emplastrum opii and emplastrum aconiti. About a month later, a spot of blood was found upon the woman's 'under-garment;' it had oozed through the pores of the sheepskin upon which the plaster was spread. Five days later, 'the tumour ruptured externally at its most anterior portion, and it was stated that the stream of blood was about the size of a lead pencil, and that after she had lost about a quart of blood it suddenly stopped.' The hæmorrhage returned at intervals of one or two days during the next sixteen days, at the end of which time the patient died of exhaustion, without any suddenly fatal loss of blood. She had suffered excessive pain since the rupture. It had been found, on examining the tumour three days before her death, that a mass of laminated fibrinous clot protruded from the rent in the wall of the sac anteriorly, and that blood-serum had been oozing through it. This mass increased before the fatal termination until it was ten inches in circumference, and protruded three inches beyond the sac.

On *post mortem* examination, an aneurism was found, commencing about one and a-half inches above the aortic opening, and terminating at the beginning of the thoracic aorta, involving the whole of the arch. The innominate artery was much dilated; a second dilatation existed at the root of the right common carotid; and in the third portion of the arch, on its outer and left side, was another marked dilatation as large as half a walnut. The relations of the aneurism to the anterior wall of the chest are thus described. 'The anterior margin of the sac is attached to the sternum at the point of erosion, and when it became perforated, and until the skin ruptured, the skin and cellular tissue formed the upper and anterior portion of the sac-wall. The whole of the sac is filled with a very solid clot, which extends through the sternum; and by its pressure forwards the skin and cellular tissue were absorbed, until the skin parted, when it protruded, thus plugging the orifice.' The clot burrowed for a considerable area around the opening in the sternum. The heart was one-third less than the normal size; the valves were competent.

The treatment of the case varied considerably during its course. When first seen, the patient was ordered to rest as much as possible, but this she would appear not to have done, and in the sixth year of her illness she was confined of a child; the labour is reported to have had no influence upon the tumour. Iron and digitalin were taken irregularly for the first three years; ergot internally and an opium plaster locally were next prescribed for a year, and for the next three years iodide of potassium was given in doses varying from five to ten grains three times a day. But this also was for some time taken irregularly. Opium, belladonna, cannabis Indica, and veratrum viride, were severally combined with the iodide from time to time. When the rupture of the aneurism took place, a plaster had been applied as described, and liquor ferri subsulphatis dilutus (two parts to one of water) was found to control the oozing. Morphia was now freely given.

The local application of the iron salt appeared to check the hæmorrhage for the time at each return; but at last the coagulum was washed away as soon as it was formed.

WILSON ON SUDDEN DEATH FROM ANGINA PECTORIS.—Dr. John Wilson describes a case in which sudden death, under peculiar circumstances, was probably due to angina pectoris (*Edinburgh Medical Journal*, September, 1874).

A farm servant, aged twenty-three, went out of a warm room into the intensely cold air of a January night, apparently quite well. About twenty minutes later he was found lying dead on his face, with his arms outstretched.

Post mortem, the heart lay flaccid in the pericardium; it was of a red flesh colour, and had a slight deposit of fat about its base. The cavities were found empty; all the valves, on minute examination, were found quite healthy. While the walls of the ventricles were a degree thicker than usual, those of the auricles were abnormally thin. There was no disease of the large vessels or of the coronary arteries. The heart was removed for microscopic examination. The lungs were congested and partly pneumonic. The condition of the other viscera was not remarkable.

The history given of the man was, that on the day preceding his death he had complained to his brother that he had been seized with an intense pain in the breast, striking through to the back, and so severe had it been that he had to stand and hold his breath until it passed away. For two or three weeks previously, he had been suffering from a cold and a hard cough. His health was believed to have been perfect up to that time. Before leaving the house, as described, the man had partaken heartily of a supper of tea and bread. At the moment of his death, it would appear that he was walking downhill with an empty pitcher in each hand.

Dr. Wilson is of opinion that death occurred in this case from angina pectoris. He remarks that the age, twenty-three years, is one of the earliest on record. He suggests that the sudden change of temperature, and exposure to the full force of a bitterly cold north wind, may have caused a reflux of blood from the external surface of the body to the heart and lungs, and induced the attack.

J. MITCHELL BRUCE, M.D.

FORREST ON CHRONIC GASTRALGIA CURED BY THE NITRITE OF AMYL.—This case, reported by Dr. W. H. Forrest in the *New York Medical Journal* for February, 1875, was a very acute one. Doses of three drachms of Magendie's solution of morphia had failed, as had also a great number of other remedies. Dr. Forrest then first tried the nitrite of amyl by inhalation, and, obtaining a slightly relaxing effect only, gave the drug by the mouth in a dose of two and a-half minims. The first method, although exhibiting most of the characteristic effects of the medicine, failed to stop the pain, which end however, was obtained by the second, in precisely eight minutes. The patient walked off, declaring that he felt peculiarly strong. The spasm, thus cut short, remained absent for about twenty-four hours, but the pain returned in full vigour. The experiment was again resorted to in like manner as at first, the dose by the mouth being increased to three-and-a-half minims. The pain ceased as before, and did not return to an extent sufficient to cause anything

but a slight annoyance. In order to relieve the sleeplessness of the opium-habit, chloral and bromide of potash were given with good effect.

Dr. Forrest then made one attempt to remedy the anæmia from which the patient suffered, by a mild chalybeate, but desisted, and left his re-establishment to nature. The patient made rapid progress, and at the time of the report was well able to do light work.

SURGERY.

VERNEUIL ON THE TREATMENT OF ANEURISM.—In the *Bulletin de Thérapeutique*, October 25, 1874, we find an interesting *résumé* of a communication from M. Verneuil, to the Société de Chirurgie at their sittings of July 29 and August 5. This comprised the history of seven cases.

The first was that of a man aged forty-two, suffering from a popliteal aneurism of only a few weeks' duration. Flexion of the limb suspended the pulsation of the tumour. This treatment (whether voluntary or forced flexion is not stated) was continued during fifteen days in an intermitting manner, as the patient could bear it, from one to three or four hours each day. The tumour diminished considerably, and lost its bruit, but continued to pulsate. Finding now that complete extension stopped the pulsation, M. Verneuil placed the limb in an immovable apparatus in the extended position, and the patient walked on crutches; but three weeks of this treatment produced no benefit. Then the patient resolved to submit to forced flexion for eleven hours, in sittings of half-an-hour at a time, with intervals of two or three minutes. This rendered the cure complete and permanent.

Case 2 was also one of popliteal aneurism, in a man aged thirty-nine, with atheromatous arteries. Forced flexion was employed five or six times a-day, in sittings of from ten minutes to half-an-hour, for twenty-two days, the patient taking digitalis and chloral. This having failed, the femoral was compressed in the groin with a shot-bag of 9 lbs. for six hours a-day, but it is not said for how many days; and then with the finger for eleven hours on two successive days. The tumour was very much reduced, but not quite cured. The cure, however, was completed during the next four days by alternations

of forced extension, in sittings of ten minutes, compression with the shot-bag in sittings of twenty-five minutes, and forced flexion in sittings of fifteen or twenty minutes.

Case 3 was one of traumatic aneurism of the radial in the middle of the fore-arm, which was cured by the application of instrumental compression to the radial at the upper third of the fore-arm for twelve hours on the whole during two days, assisted by the patient himself compressing the brachial at the bend of the elbow during the intervals.

Case 4 was one of traumatic aneurism of the superficial palmar arch, caused by an incision which had been made for the relief of diffuse inflammation. (The aneurism was attributed by M. Verneuil not to direct wound of the vessel, but to inflammatory softening of its walls.) As soon as all active general symptoms had subsided, an attempt was made to treat this by immediate compression on the tumour, compression of the radial and ulnar arteries, and compression of the brachial, all at once. This was carried on for fifteen days; but, it did not cure the aneurism, which, on the contrary, threatened to burst. Solution of perchloride of iron (twenty per cent.) was then injected. The brachial was compressed, and four drops were first injected, and then four minutes afterwards a similar quantity. In a quarter of an hour the expansile pulsations had ceased, and in a month the cure was perfect.

Case 5 was one of spontaneous popliteal aneurism in a man sixty-five years old. Forced flexion was tried, but without benefit; nor were digital compression in the groin and compression with a shot-bag more successful; and this failure was attributed to atheroma of the arteries. The patient complained much of the pain of the compression. Coagulating injections were then tried; first, of six drops of a solution of fifteen per cent. of perchloride of iron, which produced some amelioration; but a month afterwards the aneurism was as before; next, of seven drops of a solution of twenty-two per cent., which was painful, but produced a good deal of coagulation; and, finally, of eight drops of 'iodo-tannic solution,' compression being made above and below the sac for one hour and twenty-five minutes. This operation was disastrous; the leg mortified, evidently from embolism of the tibials, pyæmia supervened, and the patient died fifteen days afterwards. M. Verneuil blames himself in two particulars for the treatment of this case, viz. (1) that he did not persevere with the use of the perchloride instead of the iodo-tannic solution, and (2) that he did not amputate at once on the occurrence of gangrene. Besides (as he most truly observes), the case shows that, on the failure of compression, it would have been safer to have recourse to the ligature.

Case 6 was one of spontaneous popliteal aneurism in a man thirty-two years of age. The aneurism had existed for a year, and was of very large size. Flexion not having much effect on the aneurism, the treatment by pressure with a shot-bag in the groin was commenced, and this was continued in an intermittent manner for some days for about two hours a-day, but the sac continued to increase, and became inflamed, the inflammation extended to the knee-joint, and the whole thigh began to be cedematous and inflamed. Amputation was performed as a last resource, but the man died in a few hours. The extreme pain which preceded this fatal inflammation appeared to depend on the pressure which the rapidly growing aneurism was found to be making on

the peroneal nerve. The sac of the aneurism was very thin, and was filled with soft clot. In commenting on this case, M. Verneuil says that either total compression should have been made so as to fill the sac at once, or the ligature should have been used. [He intimates also that the old method by opening the sac might possibly have been best, but gives no reason for this conjecture. As the man was in perfectly good health before the commencement of treatment, there seems no reason why the Hunterian operation should not have proved successful, as it has done in many other cases of aneurism, even more voluminous and more rapidly growing than this.—*Rep.*]

Case 7 was one of aneurism of the femoral in Hunter's canal, in a man aged forty-seven, following on the kick of a mule, and believed to be diffused, that is, to have followed the rupture of the sac of an ordinary aneurism. Compression by means of a shot-bag having been tried, and failed, before his admission into hospital, and the man being in a bad state of health, with inflammation of the knee-joint, and œdema of the leg, the femoral artery was tied at once. The operation was performed 'below Poupert's ligament,' i.e., we presume, on the common femoral artery. The patient slowly recovered, and the general health became re-established. The tumour was reabsorbed without suppuration in five months. From this and some of the other cases, M. Verneuil concludes that pressure on the vein, causing capillary obstruction, and hence increased arterial tension, is the cause of rupture in many cases of aneurism, and that this danger and that of inflammation of the sac may often be averted by the timely use of the ligature.

M. Verneuil thus sums up his series.

Compression succeeded twice and failed four times; it was abandoned in two of the cases on account of the pain, and in the other two because it produced no good effect. M. Verneuil believes that it is better borne when made with a bag of shot than with any other mechanical means. [Few surgeons will share this opinion, unless by 'mechanical means' the author intends to exclude digital pressure, which is certainly more easily tolerated by most people; and, even if restricted to mechanical pressure in the narrower sense, the opinion is one on which much doubt is permissible.—*Rep.*] Pressure in general, M. Verneuil says, 'is an imperfect method, and sometimes hurtful.'

Flexion was twice beneficial, once curative by itself. In two other cases it failed.

Extension is, in M. Verneuil's opinion, useful to a slight extent as an adjuvant.

Coagulating injections were only once successful (viz. in Case 4). The method is difficult to practise and very dangerous. In old people it should not be tried. The perchloride of iron is the only agent which should be employed.

The ligature in the only case tried was extremely successful, but M. Verneuil's personal experience of this treatment is not sufficient to enable him to speak from his own experience. He thinks it dangerous to attempt primary union of the wound. [We have no doubt that further experience would reverse this opinion.—*Rep.*]

Amputation should be reserved for cases of the most grave nature—gangrene, diffuse inflammation, arthritis, rupture of the sac, and hæmorrhage; but when the indication is distinct, the operation should not be deferred.

As an appendix, a communication is given from M. Demarquay to the Société de Chirurgie, on the treatment of aneurism in old persons—the conclusion of which is that, when the arteries are atheromatous, both the ligature and flexion are very dangerous, and that the best plan is to employ digital pressure in a mild form, assisted by elastic support to the aneurism.

Finally, the narrator of the case quotes from the *British Medical Journal*, August 8, 1874, the conclusions of the present writer on the treatment of popliteal aneurism, which nothing in the present series of cases tends to negative. The chief points are as follows.

1. In rapidly growing aneurism with thin sac, especially if traumatic, the ligature should be early practised (see Case 6).

2. The success of the ligature has been much greater in the hospitals of Great Britain of late years than the published statistics show to have been the case in earlier times.

3. In hospital practice compression has not been more successful than the ligature—though no doubt it might be made so by greater care in its application.

4. It is well not to insist too long on compression, if it do not at once produce some considerable improvement.

5. Flexion should be tried when it acts powerfully on the pulsation of the tumour, but should not be used in a painful manner, nor too long persevered in.

6. There is no proof of the utility in popliteal aneurism of the less common methods of treatment, such as galvanism, coagulating injections, manipulation, the temporary ligature, or the introduction of foreign bodies.

MARQUES ON THE CURE OF AN ANEURISM OF THE RIGHT EXTERNAL CAROTID ARTERY BY DIGITAL COMPRESSION.—Dr. Marques, of Lisbon, lately reported this case to the Academy of Medicine of Paris (*Gazette Médicale de Paris*, February 6, 1875, and *Gazette Hebdomadaire*, February 5). The case is also published at length in the *Correio Medico de Lisboa* for January 9.

The patient was a gentleman, aged thirty, resident in Bahia. About November, 1873, he began to feel pain in the right side of the neck and the right ear. The pain was intermittent, and did not give him much trouble. On August 31, 1874, a medical man saw him for the first time and detected an aneurism. An attempt was made to cure him by digital compression on the common carotid, for nine hours a day during the first ten days, and for ten or twelve hours during the next twenty-nine days, aided by the application of a bladder full of ice to the tumour, and the internal administration of digitalis and hydrate of chloral. Under this treatment the tumour became much harder and somewhat smaller, but still pulsated. He embarked for Lisbon on November 6. He suffered a good deal on the voyage from sickness, which he attributed to the use of digitalis, and which ceased on his giving up taking that drug. He continued to use chloral. From this time he suffered a good deal from pain in the tumour and in the ear; it increased much in intensity, but ceased on the use of some soothing lotions after his arrival in Lisbon. He was admitted into the Maison de Santé at Lisbon on November 15. The tumour at this time was oval, measuring seven or eight centimètres (rather more than two inches)

in the smaller diameter, with its lower end behind the angle of the jaw and its narrower in connection with the right lobe of the thyroid gland below, touching the thyroid cartilage on its inner and the sterno-mastoid muscle on its outer side. It had the usual pulsation and bruit of aneurism, which were at once stopped by compression of the common carotid. The veins of the part were somewhat dilated. There were no morbid sounds in the heart or lungs. The diagnosis was 'a false consecutive aneurism,'* of the right external carotid; and it was agreed that a renewed attempt should be made to cure it by compression. This treatment was commenced on November 21, after six days' rest and medical treatment. The compression was made for seven hours by the medical men and male nurses of the *Maison de Santé*, the patient being in the sitting position. The common carotid was compressed against 'Chassaignac's tubercle,' *i.e.* the anterior tubercle of the transverse process of the fifth cervical vertebra. In half an hour the patient became giddy, and soon afterwards fainted; and after this the compression was made in the horizontal posture. After forty days of treatment, comprising on the whole 283 hours of compression, the pulsation gradually disappeared, and the patient was completely cured. Two points which were observed during the process strike the reporter as of considerable interest. One was that on December 15 it was remarked that the tumour had a feeble pulsation, even when the carotid was completely compressed, and it was discovered that this was due to pulsation in the superior thyroid artery, from anastomotic circulation. Another was, that after the definitive cure of the tumour (on December 30) pulsation could be perceived above the tumour, in the upper part of the external carotid, which was evidently due to anastomotic circulation, since it was not checked by compression on the common carotid of that side. The account refers to a collection made by the present reporter of seven cases of compression of the carotid for aneurism in the neck. In two cases it failed, and the carotid was tied, with a fatal result in each case; in the other five it succeeded, four being cases of digital, and one of instrumental compression. This is therefore the fifth successful case of digital compression of the common carotid for aneurism in the neck.

AUDÉ ON A CASE OF TRAUMATIC FEMORAL ANEURISM CURED BY THE LIGATURE OF THE ARTERY ON ANEL'S METHOD.—Dr. A. Audé relates, in the *Bulletin de Thérapie*, February 15, 1875, a case which occurred in 1872, in a man aged twenty-nine, who accidentally stabbed himself in the thigh. The hæmorrhage was very violent, but was restrained by pressure. He was admitted next day into hospital,

* Is it allowable to express a hope that some more intelligible language may get into use in describing aneurisms? The present writer has read and written much on aneurism, yet he must profess his entire uncertainty what is meant here by the terms 'false' and 'consecutive.' It might be that the consultants thought that the tumour had been ruptured during the voyage in the efforts of vomiting, and therefore called it 'consecutive,' and also that it had originally been formed only of the external coat of the artery, and therefore denominated it 'false;' but there is no indication of this in the Portuguese narrative. The narrators (the surgeons of the *Maison de Santé*) speak of the 'constantly gradual progress of the aneurism' during the voyage, and of its having enlarged both in outward direction and towards the pharynx. —*Rep.*

very pale from loss of blood, and suffering much from pain in the thigh. On the bandages being removed next day, *i.e.* the second after the accident, a vertical wound was found about an inch in length at the junction of the lower and middle third of the thigh, over the course of the artery. The whole thigh was enormously swollen, and pulsation could be felt over the whole of the anterior part of the limb, from its centre to about an inch above the internal angle. There was also very loud rasping arterial bruit. Pressure on the femoral in the groin suppressed the pulsation and bruit at once. The pulsation in the arteries below was perceptible, though very feeble. During the examination the tumour became more prominent, and it was necessary to do something at once. The surgeon thinking that it was out of the question to attempt to tie the artery above and below the wounded part (though he does not explain his reason for thinking so), and considering that the Hunterian ligature was too uncertain, and in the patient's condition too dangerous, determined to continue the pressure, in the hope that (as he expresses it) 'the diffused primitive aneurism might transform itself into a false consecutive aneurism,' *i.e.*, in simpler language, that a complete sac might form. Accordingly, a tourniquet was loosely applied over the femoral above, and compresses and bandage to the wound. The sac formed accordingly, the tumour becoming more defined, though it was still of very large size, and about five weeks after the accident, as the aneurism had begun to increase, and the wound began to open out and threaten hæmorrhage, it became necessary to operate. The superficial femoral artery was therefore tied just above the tumour, and about an inch below the origin of the profunda. Dr. Audé remarks that the pulsation of the popliteal had long ceased to be perceptible, yet the limb continued to be perfectly nourished, which led him to believe that the collateral circulation had already been re-established. The case did perfectly well, except that the aneurismal sac suppurated, and it was necessary to lay it freely open; and in a few months the man returned to his employment, that of pointsman on a railway.

[We have thought this worth quoting as an example of the success of Anel's operation,—an operation rarely performed now-a-days on the femoral artery. The motive of the surgeon for postponing the ligature of the vessel above and below the wound, which would otherwise seem certainly the most obvious treatment, appears to have been the exhaustion of the patient at the time of the accident. It will be noticed, however, that this delay did not save the patient from the necessity of ultimately laying the sac open.—*Rep.*]

T. HOLMES.

ROUX (DE BRIGNOLES) AND PAULET ON URINARY FEVER.—At the Society of Surgery in Paris, on December 9, 1874 (*Gazette des Hôpitaux*, January 12, 1875), M. Paulet criticised a paper by M. Roux on the origin of urinary fever. The author's views on the causes and nature of this disease have some interest. To predisposing causes he assigns little weight, and classifies nephritis, which some hold to be the real cause of the symptoms in all cases, with diarrhœa, rheumatism, etc. As determining causes, he maintains two factors to be essential—an alkaline or partially decomposed urine, and a laceration of the mucous membrane of the urethra, over which the alkaline urine must pass. He describes the production of the

fever as follows. Let a patient have a strictured urethra; if behind the impediment there be no ulceration or breach of surface secreting a mucopurulent discharge, the instruments necessary for evacuating the bladder or dilating the contraction may be passed without causing urethral fever or other inconveniences. But should the catheter, in threading its way through the contractions, tear a fold or chafe the projecting or ulcerating points in the distended urethra behind the stricture only sufficiently to cause a very slight bleeding, the door is opened to absorption of septic matter from the disorganised urine, and urinary fever takes place. M. Paulet questions the accuracy of this explanation. He allows that alkaline foetid urine is a necessary condition, believing that true urinary fever does not occur when the urine is normal; but he maintains that the evidence brought forward by the author, to show that the septic absorption can take place only through the lacerated urethra behind the stricture, is insufficient. Paulet holds that urinary fever, though far most frequent among strictured patients, does also occur in cases of chronic cystitis where the urethra is healthy and empties itself during micturition to the last drop. He points out that the observations of Küss and Jusini prove that the vesical epithelium, in its healthy state, has very little, if any, absorbing power; but that alkaline urine softens and disengages the epithelial cells from each other, so that, even if the mucous membrane be not quite bare, the mere touch of the sound causes an erosion and opens the door for the entry of urinary poison. If this be correct, and the septic agents of decomposed urine can be absorbed from other parts of the urinary tract and not solely from the urethra, Paulet desires that the name urinary fever should be retained, instead of urethral fever as proposed by the author.

With regard to the nature of the toxic agents, to whose introduction into the circulation urinary or urethral fever is due, Roux believes them to be ferments, because the alkaline urine is usually highly charged with multiplying germs of the torulaceous class. In short, urinary fever is a zymotic affection due to fermentative poison, and not simply to absorption of carbonate of ammonia into the blood.

Uræmia from parenchymatous nephritis or pyelonephritis, often present in long-standing affections of the bladder or urethra, is held by M. Roux to be so distinct by its symptoms from urinary fever that it cannot be confounded with the latter. Paulet does not admit this. He points out that, although a well-marked case of uræmic convulsions has little in common with urinary fever, yet many of the manifold forms of uræmic poisoning merge in a manner not to be distinguished from cases of urinary fever. If the occasional similarity of uræmic poisoning and urinary fever be granted, he is ready to allow that usually these two affections are unlike each other. Paulet, regretting that the author has devoted but little of his treatise to the part played by kidney-affections in producing septic urinary poisoning, declines to agree with Malherbe and others who ascribe both urinary fever and uræmia to them alone, to the complete exoneration of the bladder and urethra. Malherbe formulates his theory as follows. In uræmic or urinary fever the symptoms may be divided into the reactionary, or those due to inflammation of the kidney, and those due to intoxication from retention of the materials of the urine in the blood. The more violent attacks, resembling ague, are caused by

intense renal congestion; the remittent form accompanies interstitial nephritis. In other words, to borrow those of Girard, the conditions described under the name of urethro-vesical fever, or urinary intoxication, may be attributed to two causes; (1) The accumulation in the blood of the constituents of urine through the excretive function of the kidneys being impeded or abolished by injuries of the acini; symptoms that are identical with uræmia in Bright's disease; (2) Absorption of decomposed urine; symptoms analogous to those of putrid intoxication. Paulet prefers to occupy a position between Roux and Malherbe, believing that, though not constantly, the kidney is often combined with the bladder as the seat of inflammation in urinary fever.

In his directions for treating urinary fever, Roux urges early cure of vesical catarrh if it be present; the administration of bromide of potassium to diminish the sensitiveness of the urethra; and he sets high value on quinine, and especially on alcohol, as a means of reducing fever. He also, from a small number of experiments, believes that thirty grains (two grammes) of ergot given before the catheter is passed tends to prevent fever. During the progress of the fever, Roux gives most confidence to quinine and alcohol in considerable doses.

OBSTETRICS AND GYNÆCOLOGY.

CREMONESI ON A CASE OF INTERSTITIAL CYSTIC SARCOMA OF THE UTERUS, MISTAKEN FOR OVARIAN TUMOUR.—Dr. Cremonesi relates the following rare case in the *Archivio di Medicina, Chirurgia, ed Igiene*, November and December, 1874 (*Gazzetta delle Cliniche*, February 2.)

A. P., aged fifty-two, mother of a large family, had ceased to menstruate for three years, and during that time had been subject to nervous disturbances such as accompany pregnancy. The abdomen increased in size; two or three months after the last catamenia, she had an attack of metrorrhagia; and after that, the loss of blood from the uterus recurred at irregular intervals, became in course of time more

frequent and abundant, and reduced the patient to a deplorable condition.

When admitted into hospital, under Professor Laurenti, on August 7, 1874, she had a large abdominal tumour, extending from the pubes to above the umbilicus. It projected most at the umbilical and right epicolic regions, was elastic, and slightly painful on pressure; on palpation, it was found to contain fluid; on percussion a sharp sound was heard; and auscultation revealed a soufflé isochronous with the pulse. A sound introduced into the uterus did not pass beyond 0·8 to 1·2 inches. Dr. Laurenti believed that the case was probably one of ovarian cyst. A puncture gave exit to about a pint and a half of liquid. The abdomen became smaller, but the tumour did not disappear. It was then believed that the cyst was multilocular, and ovariectomy was decided on. The next day, however, the abdomen had become as large as before; vomiting and diarrhoea set in, the metrorrhagia became more profuse, and the patient died on August 17.

At the necropsy, the ovaries were found to be healthy; the tumour was uterine. The cervical portion of the uterus was dilated and elongated; the cavity of the organ was much distended, and the thickness of the walls gradually diminished from below upwards, being at last only four or five millimètres (0·16 to 0·2 inches). It appeared as if the uterine cavity was completely divided into two unequal parts by a horizontal septum, formed by the detachment of some of the more internal muscular strata of the uterus. The upper portion was the larger, and formed about three-fourths of the whole. The lower portion, which represented the true uterine cavity, was covered with mucous membrane and communicated with the cervical canal. In the upper cavity was a new growth, arising from various points of the wall, and of different forms and sizes in its various parts. To the right of the cavity was a cylindroid mass, free, and about $5\frac{1}{2}$ inches long, and another mass was united to the wall on the left side by a very slender bridle. The portion of the cavity not occupied by the tumour contained a yellow albuminous liquid, like that which had been removed by puncture.

Microscopic examination showed that the tumour was a sarcoma developed in the uterine walls.

A. HENRY, M.D.

GOLDSCHMIDT ON CARCINOMA OF THE FUNDUS UTERI.—Herr Goldschmidt reported four cases of carcinoma of the fundus uteri at the Obstetrical Society of Berlin, meeting on March 24, 1874 (*Berliner Klinische Wochenschrift*, no. 52, 1874). The diagnosis of this complaint is rendered difficult from its being accompanied through its various stages with symptoms which belong also to other uterine ailments, and added to that the rarity of carcinoma of the fundus may easily lead it to be mistaken for the other affections. It is complicated with discharges, swellings, alterations of position and inflammations in the neighbourhood. A microscopical examination of the discharges might frequently aid the diagnosis.

The first case was that of a sterile woman, aged forty-two, who had suffered in the lower part of the abdomen for six years. She was first seen by Herr Goldschmidt for symptoms of obstinate constipation, with signs of ileus. An examination discovered that the rectum was completely compressed by the uterus,

was changed into a strong hard tumour of the size of a fist. Injections *per rectum* had no effect; and it was only after division of the sphincter and the introduction of the whole hand, and pushing the uterus forwards and replacing a fold of mucous membrane that had become displaced above it, that complete emptying of the bowels took place. After that, the operation had to be frequently repeated. At the end of a year, when the case was related, canceroid degeneration had appeared in the vaginal portion of the uterus in the vagina; the fundal tumour was probably the starting-point of the disease.

In a second case there was also enlargement and compression of the rectum; cancer-cells were found in the discharges. A third case was seen just before death. The rectum was compressed in the same way; and the necropsy showed carcinoma of the fundus, of the abdominal parietes, and of the ovaries. In a fourth instance, beyond a foetid discharge and some erosion, nothing was to be found in the uterus; nevertheless, the microscope showed cancer-cells in the discharge. Herr Wegscheider considered the diagnosis of cancer of the fundus extremely difficult, and that it had not been established in the three cases where the necropsy had not been made. He personally had only met with one case of cancer of the fundus, which was first discovered in the *post mortem* examination. In this case there was a probability of its having passed from the bowel to the uterus.

Herr Wernich found, in the cases described, a similarity with those of sarcoma recorded by Gussierow, Hegar, Spiegelberg, and Chrobak; and was disposed to assume that Dr. Goldschmidt's were also cases of sarcoma. He himself had up to this time only met with one case.

Dr. Goldschmidt laid great stress on the microscopic results as a diagnosis.

STOLTZ ON FIBROIDS OF THE UTERUS: INTRA-UTERINE MYOMATA.—M. Stoltz, writing in the *Revue Médicale de l'Est*, February 1, 1875, says that pediculated fibrous bodies, commonly known by the name of polypi, arise either from the cavity of the body or from the neck. The former are not properly pediculated, but adhere to a more or less limited surface of the uterus; they are really sessile. They become pediculated by the excessive uterine efforts at their expulsion. When in the vagina, they are not really pediculated. Should the part to which they are attached offer considerable resistance, the capsule may become elongated into a veritable pedicle. As a rule, the fibrous body draws down with it the portion of the uterine wall to which it is attached, causing an inversion of the uterine parietes, allowing thereby the polypus to project into the vagina. This fact should never be absent from the mind of the operator, whether the polypus be still within the uterine cavity or protruded into the vagina, or replaced into the uterus, or drawn down by the manipulator into the vagina. The first object is to make out whether the tumour is pediculated or sessile; if the latter, the extent of the base. Should it prove to have a wide base, he strongly recommends making a couple of incisions into the capsule with a pair of curved scissors; the tumour then peels out of its capsule as the rind does from off an orange. He has done this operation many times with success; as a rule, it is the most expeditious and least dangerous method of dealing with these growths; but he admits exceptions. The wire *écraseur* he objects to, on account of the danger of cutting the uterus, which

has been the case more than once in the hands of the most skilled operators. Professor Braun-Fernwald, for the same reason, advises the tumour to be cut in halves, or a piece cut out of it with the galvanic wire cautery. Other authors strongly recommend that the patient should not be anaesthetised before tightening the wire of the écraseur, as, from the uterine tissue being a sensitive structure, her sensations will be a fair guide as to whether the uterus has been impinged upon or not.

W. C. GRIGG, M.D.

BLACKWOOD ON QUININE AS AN OXYTOCIC.—Dr. Blackwood of Philadelphia states (*Philadelphia Medical and Surgical Reporter*, Jan. 1875) in reference to this vexed question, that, during a residence in a part of the States where intermittent fever abounded, he met with clear and unmistakable proofs of the power of quinine to excite the uterus to action. In several instances, when he gave it to pregnant women who were suffering from ague, abortion was quickly induced, though the patients were in fair health, and had previously had no tendency to miscarriage. He is of opinion that intermittent fever itself does not predispose to abortion, and he was so satisfied that the quinine was to blame, that in similar cases he afterwards substituted arsenic for it, and had no more such accidents. Dr. Blackwood has also tried quinine experimentally in cases of labour, and he states that its effect is uncertain, but that, in some cases, its action is as decided and prompt as ever he has obtained from ergot; in one case, where ergot acted inefficiently, quinine gave much more satisfactory results.

J. W. LANGMORE, M.D.

PAJOT ON CHLOROFORM IN NATURAL DELIVERIES.—Professor Pajot, while discussing Dr. C. J. Campbell's work, of which an analysis was given in the *Bulletin de Thérapeutique*, vol. lxxvi. p. 234, comes to the following conclusions. The place of chloroform in obstetrics is now definitively settled. No practitioner would hesitate to use it with all indispensable precautions in cases of painful operations or abnormal though spontaneous deliveries, unless there be indications to the contrary. True anaesthesia, however, when used in natural deliveries during the periods of uterine and vulvular dilatation, is a serious and scientific process which admits of discussion; its dangers and inconveniences appearing to exceed its advantages in the opinions of some persons, though there are arguments for the opposite view and it is capable of defence. As to the so termed semi-anaesthesia, it is a practice as useless as it is harmless, and has no scientific or serious value whatsoever. Such are the opinions of M. Pajot, who, in the *Annales de Gynécologie* for January 15, 1875, likewise attacks some passages in Dr. C. J. Campbell's memoir.

PSYCHOLOGY.

BLANCHE, BERGERON, AND LASÈGUE ON IMPULSIVE INSANITY.—In the *Archives Générales de Médecine*, January, 1875, there is a report by Drs. Blanche, Bergeron, and Lasègue of a homicide committed by a young man, Henri Thouviot, the victim being a girl aged twenty, an assistant at a restaurant, whom he had never seen previously to the moment when he stabbed her. Questioned why he did it, he replied that it was to satisfy an idea which he had had for a long time, and said further that he had passed the preceding night with a girl whom he had intended to kill, but had desisted, chiefly because he feared that he would be suspected of murdering her for the sake of robbery. The reporters review the various kinds of homicidal insanity, which they describe under four heads. 1. Homicide through delusion, e.g., that a system of persecution is being carried on. Thouviot had had an idea that his mother was responsible for his misfortunes and want of character, and had conceived some idea of murdering her, but this form was not that under which he stabbed the girl at the restaurant. 2. A weak-minded or imbecile individual may commit a murder after some slight quarrel or fancied provocation. Thouviot cannot be brought under this category. 3. An intermittent or transitory mania is sometimes found, depending on alcoholic poisoning, on epilepsy, or on a masked epilepsy. Thouviot exhibited no affection of the muscles or of speech; and although the pupils were unequal, and the sight of the left eye impaired, it was thought that there was no brain-lesion. He had had some attacks of vertigo, but there seemed no reason for thinking him an epileptic. 4. There is, however, another class of insane homicides impelled to commit murder by an irresistible though transitory power, without other physical or psychological lesion at the time, without subsequent defect of intellect. Such attacks may be more or less intense and more or less frequent. They may not recur for years; they may be instantaneous, passing quickly away, or may continue for days or weeks. There is no loss of consciousness or of recollection, as in epilepsy. Thouviot, according to the reporters, belonged to this category. His demeanour was different from that of ordinary criminals; he discussed the crime as if it was another's. He was vain of the name of 'assassin,' puerile in his ideas and wishes, without any power of reflection. He was transferred to Bicêtre.

AUZOUY ON MASKED EPILEPSY.—In his account of a criminal case, in which masked epilepsy was alleged in defence, Dr. Auzouy (*Annales Médico-Psychologiques*, Nov. 1874), remarks that the doctrine of this disease involves some of the most delicate and difficult questions of legal medicine. It is, according to some, a neurosis which is not to be recognised by any external symptoms, or by any forewarning, but which is manifested by sudden and violent acts, repeated at varying intervals, and yet demanding entire irresponsibility. But, he says, although it is not declared by the ordinary epileptic attack, or by unmistakable external symptoms, it has, nevertheless, characteristic marks by which it may be known. Trousseau tells us that the epileptic act in such patients is even more sudden than the convulsive seizure, and is evidenced by some extraordinary or outrageous conduct, which one sees

cannot be voluntary. M. Falret says that, in these epileptics, slight convulsive movements may be noticed by a medical man, which might escape ordinary observation. And further, he quotes M. Morel, who lays down the following as characteristics of the disease: Periodical exaltation, followed by prostration and stupor; exaltation of sensibility; acts having the character of instantaneous and irresistible impulse; tendency to suicide and homicide; delusions and cerebral excitement; exaggerated ideas of strength, riches, and intellect; mixture of erotic and religious sentiments; frightful hallucinations, dreams, and nightmares; gradual weakening of intellect, loss of memory of what was done in the paroxysm; delusions recurring in the same way on each occasion. Dr. Auzouy tests the alleged epileptic by these characteristics, and decides that they were not to be found in him. The man was accused of indecent conduct with boys, and this extended over a period of fifteen years; and so long a time proves, he says, conclusively, that it was not masked epilepsy. Another man was accused of acts of immorality with little girls, and he tests him in the same way, and decides against the theory of his being an epileptic. He quotes M. Billod, who says that the only sure test of an epileptic attack is the want of recollection of what was done during it, and that, in the absence of this, a prudent reserve must be maintained. That masked epilepsy does render patients irresponsible must, he says, be admitted by all; and therefore it is the more necessary that the characters and principal symptoms should be laid down in a lucid and unmistakable manner.

Remarks on the Origin, Varieties, and Termination of Idiocy. By Dr. Grabham. (*British Medical Journal*, January 16.)

ELECTRO-THERAPEUTICS.

WAGENHALS ON INSULATION OF BEDS.—Dr. Wagenhals, of Columbus, Ohio (*The Philadelphia Medical and Surgical Reporter*, January, 1875) reports a number of cases of rheumatism, in which simple insulation of the beds, by placing the legs of the bedstead in four glass tumblers, appeared to be of remarkable efficacy in easing pain, procuring sleep, and promoting recovery. He has no theory to offer as to the *modus operandi* of this treatment, but simply records the facts. In some parts of South America, along the banks of the Amazon river, families place the legs of their beds habitually into tumblers filled with water, not, as might be expected, to protect them from insects and vermin, but for the relief of rheumatism and kindred disorders, and to prevent attacks of malarial fevers. [A French army surgeon, who found years ago the same habit,

existing in Algeria, has written an elaborate memoir to prove that the benefit of the procedure is owing to the prevention of the escape of the vital electricity from the system.—*Rep.*] JULIUS ALTHAUS, M.D.

MISCELLANY.

MR. J. R. BLAKE, M.A., F.G.S., has been elected to the lectureship on Zoology and Comparative Anatomy at Charing Cross Hospital Medical School.

MR. E. RAY LANKESTER, M.A., Fellow of Exeter College, Oxford, has been elected to the Professorship of Zoology and Comparative Anatomy in University College, London, rendered vacant by the death of Dr. Grant.

ARTIFICIAL EYES FOR HORSES.—In the *Magazin für die gesammte Thierheilkunde* (1873, second part), Herr Hertwig, professor at the Berlin Veterinary School, describes an improvement in the artificial eyes which are sometimes employed, particularly on the Continent, to palliate the unsightliness resulting from the extirpation or atrophy of the horse's eye from accidental causes. Horn is the material out of which he has fabricated the artificial eye, which is merely a smooth capsule or shell of this substance. The effect of an artificial eye of this description, especially when seen at a distance, is astonishing; indeed, the illusion is complete, for it looks exactly like a real eye, and the natural appearance of the horse's face is quite restored. The eye is easily maintained in the orbit, and rarely causes an increased mucous secretion or any other untoward effect. The horse does not object to it; indeed, it is a comfort to the animal, as it prevents the entrance of flies, dust, and other injurious bodies to the cavity. Hertwig gives drawings of the artificial eyes. The price is about one shilling.

MARRIAGE AND LONGEVITY.—In our impression of February 10, we gave a summary of Mr. Herbert Spencer's remarks on the fallacy of the ordinary statement that matrimony conduces to length of days. Researches made by M. Bertillon tend to controvert this view; at any rate, so far as concerns France, Belgium, and Holland. A careful study of statistical documents relating to these countries, and especially to the city of Paris, show that marriage creates a remarkable increase of longevity in both sexes. M. Bertillon has likewise extended his investigations to the class of widowers, amongst whom he finds the same, or even a higher ratio of mortality, than amongst celibates of the same age. He thence concludes that the greater vitality of married persons is not derived from extrinsic causes, but is a directly beneficial result of marriage, which modifies the conditions of life advantageously. To this fact, however, there is, according to M. Bertillon, a striking exception; it is that marriages contracted before the parties are twenty years old, instead of diminishing the risks of death, increase it; for women in the proportion of seven to eleven, and for men in the proportion of seven to fifty; that is to say, from one to seven.

INCREASE IN THE DURATION OF LIFE.—In ancient Rome, during the period between the years 200 and 300 A.D., the average duration of life among the upper classes was thirty years. In the present century, among the same classes of people it amounts to fifty years. In the sixteenth century the mean duration of life in Geneva was 21.21 years, between 1814 and 1833 it was 40.68 years, and at the present time as many people live to seventy years of age as three hundred years ago lived to the age of forty-three. In the year 1693 the British government borrowed money, the amounts borrowed to be paid in annuities, on the basis of the mean duration of life at that time. The State Treasury made thereby a good bargain, and all parties to the transaction were satisfied. Ninety-seven years later, Pitt established another tontine or annuity company, based on the presumption that the mortality

would remain the same as 100 years before. But in this instance it transpired that the government had made a bad bargain, since, while in the first tontine 10,000 persons of each sex died under the age of twenty-eight, 100 years later only 5,772 males and 6,416 females died under this age. From these facts it appears, that life under certain favourable influences has gained in many and probably in all its forms and manifestations, both in vigour and duration. To still further promote this tendency, it is only necessary that those conditions under which the attainment of the desired end is possible be made to accord with the fundamental natural laws. — *Deutsche Versicherungs-Zeitung*.

SCHOLARSHIPS AND EXAMINATIONS FOR NATURAL SCIENCE AT CAMBRIDGE, 1875.—The following is a list of the scholarships and exhibitions for proficiency in Natural Science to be offered at the several colleges and for non-collegiate students in Cambridge during the present year. *Trinity College*. One or more scholarships of 100*l.*, and one exhibition of 50*l.* The examination for these will commence on March 30. Further information may be obtained from the Rev. E. Blore, tutor of Trinity College. — *St. John's College*. One of the value of 50*l.* per annum. The examination (in Chemistry, Physics, and Physiology, with Geology, Comparative Anatomy, and Botany) will commence on April 3, and will be open to all persons who have not completed a term of residence at the University, as well as to all who have entered and have not completed one term of residence. There is a separate examination in Natural Science at the time of the annual college examination at the end of the academical year, in May, and exhibitions and foundation scholarships will be awarded to students who show an amount of knowledge equivalent to that which in Classics or Mathematics usually gains an exhibition or scholarship in the College. In short, Natural Science is on the same footing with Classics and Mathematics, both as regards teaching and rewards. *Christ's College*.—One or more in value from 30*l.* to 70*l.*, according to the number and merits of the candidates, tenable for three-and-a-half years, and for three years longer by those who reside during that period at the College. The examination will be on April 6. There are other exhibitions which are distributed annually among the most deserving students of the College. Further information may be obtained of John Peile, Esq., Tutor of the College. *Corville and Caius College*.—One of the value of 60*l.* per annum. The examination will be on March 18, in Chemistry and Physics, Zoology with Comparative Anatomy and Physiology, and Botany with Vegetable Anatomy and Physiology. Further information may be obtained from the Tutors. Scholarships of the value of 20*l.* each or more are offered annually for Anatomy and Physiology to members of the college. Gentlemen elected to the Tancred Medical Studentships are required to enter at this college; these studentships are five in number, and the annual value of each is 100*l.* Information respecting these may be obtained from B. J. L. Frere, Esq., 28 Lincoln's Inn Fields, London. — *Clare College*. One of the value of 60*l.* per annum, tenable for two years at least. The examination (in Chemistry, Chemical Physics, Zoology with Comparative Anatomy and Physiology, Botany with Vegetable Anatomy and Physiology, and Geology) will be on March 16, and will be open to students attending to begin residence in October. — *Downing College*. One or more of the value of 60*l.* per annum. The examination (in Chemistry, Comparative Anatomy, and Physiology) will be on April 6, and will be open to all students not members of the University, as well as to all undergraduates in their first term. — *Sidney College*. One of the value of 60*l.*, and one of the value of 40*l.* per annum. The examination (in Heat, Electricity, Chemistry, Geology, Zoology, and Physiology, and Botany) will be on April 6, and will be open to all students who intend to commence residence in October. — *Emmanuel College*. One of the value of 70*l.* The examination on March 24 will be open to students who have not commenced residence. —

St. Peter's College. One scholarship of the value of from 40*l.* to 80*l.* according to the attainments of the candidate. The examination of April 6 will be in Botany, Chemistry and Chemical Physics, Geology, and Comparative Anatomy and Physiology; but no candidate will be allowed to be examined in more than two of these subjects. Application must be made before March 20 to the tutor. — *Non-Collegiate Students*. An exhibition each year is given by the Clothworkers' Company, value 50*l.* per annum, tenable for three years. Examination about Christmas. Information to be obtained from the Rev. R. B. Somerset, Cambridge. Although several subjects for examination are in each instance given, this is rather to afford the option of one or more to the candidates than to induce them to present a superficial knowledge of several. Candidates, especially those who are not members of the University, will, in most instances, be required to show a fair knowledge of Classics and Mathematics, such, for example, as would enable them to pass the previous examination. There is no restriction on the ground of religious denominations in the case of these or any of the scholarships or exhibitions in the Colleges or in the University. Further information may be obtained from the tutors of the respective colleges. Some of the colleges do not restrict themselves to the number of scholarships here mentioned, but will give additional scholarships if candidates of superior merit present themselves; and other colleges than those here mentioned, though they do not offer scholarships, are in the habit of rewarding deserving students of natural science. It may be added that Trinity College will give a fellowship for natural science once at least in three years; and that most of the colleges are understood to be willing to award fellowships for merit in natural science equivalent to that for which they are in the habit of giving them for classics and mathematics. The scholarships and exhibitions are open to all persons, whether members of the University or not, provided they are willing to enter and become members of the respective colleges, with the exception of the 100*l.* scholarships at Trinity College, the candidates for which must have passed the previous examination at the University.

THE LATE CANON KINGSLEY, in his interesting Lectures on Health and Education, points out the indispensability of good light and good ventilation, both being essential to health and comfort. For ventilation, lower the upper and raise the lower part of the windows (say a couple of inches), fresh air will then be allowed to enter, and the hot air will escape outwards. This will be a step towards ventilation. As to light, instead of burning gas in day time, have one of Chappuis' Daylight Reflectors fitted to your window or skylight, and at night economise one or two burners by means of shades or reflectors fitted to your brackets, &c. By paying a visit to the Factory, 69 Fleet Street, you will become acquainted with the best mode of obtaining good and cheap light. — [ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the Editor, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOSANGE, Rue Quatre-Septembre.—Leipzig: Mr. K. F. KOEHLER.—Florence: Mr. E. LOESCHER.—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19*s.* 6*d.* Cloth Cases for binding the Numbers for each year may be had for 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART.—Amsterdam: W. H. KIRBERGER.—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON.—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS.—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MARCH 17, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

HEGER ON THE CIRCULATION OF THE BLOOD IN EXCISED ORGANS.*

Dr. Heger, professor of physiology in Brussels, in an able monograph, cites the results of his researches on the above subject, made under Ludwig's direction. The author shows clearly that the alkaloids have an action, entirely local, upon the walls of the vessels, and that this action is independent of the nerve-centres.

Artificial Circulation.—An organ, such as the liver or kidney, is removed from the body as soon as the animal is killed, and a stream of blood passed through its vessels. The study of its function is therefore very greatly simplified. The blood employed ought to be defibrinated, carefully filtered, and brought to a proper temperature, and be taken from an animal of the same species from which the organ, whose function is to be studied, was taken. In certain cases, however, the blood of other animals may be employed, as the blood of the rabbit or the frog, etc. A description is then given of the manner of making artificial circulation of defibrinated blood in the lungs of a dog. The lungs are placed in a glass case, hermetically sealed, to represent the thorax; within which the pressure on the surface of the lungs is easily regulated and graduated by a pressure-bottle. Similar instructions are given for artificial hepatic secretions, just as was practised by Asp (LONDON MEDICAL RECORD, December 16, 1874). The changes that the defibrinated blood undergoes in its passage through the different organs experimented on are then considered.

General Modifications observed in Artificial Circulation.—Generally the blood in its passage loses its red arterial colour and takes on a venous character; but if the rapidity of the circulation be considerable, it passes through without alteration of colour; the absolute quantity of oxygen absorbed and of carbonic acid produced is considerable, the relative quantity less.

As the chemical modifications are dependent on the rapidity of the current, it is important to study the causes that vary the duration of passage and establish the relation between pressure and velocity.

If organs be devoid of all the properties of living tissues, the pressure being equal, then the quantity of blood obtained at the orifice of outflow will be equal in equal times, save those slight differences which are observed upon operating on inert tubes of small diameter (Poissonuille).

But it is not so in a fresh organ in which we cause a current of defibrinated blood to circulate under, *e.g.* a constant pressure of ten millimètres of mercury.

* *Expériences sur la Circulation du Sang dans les Organes Isolés.* Par Dr. Paul Heger, Bruxelles, pp. 69, 8vo, 1873.

The quantity of blood which traverses the organ becomes less from minute to minute, with, however, some oscillations. If, at the moment of cessation of the flow, the pressure in the entering vessels be suddenly elevated by several millimètres, the afflux augments immediately at the orifice of outflow, and, after having attained a maximum, gradually declines. If at the end of the outflow, before it has ceased, the pressure within the entering vessels be suspended, then the current ceases immediately; then, upon restoring the pressure, the current is more considerable than before the interruption. It is seen, then, that (1) every oscillation of pressure causes oscillations in rapidity; (2) under the same pressure, the quantities delivered are not equal, since the rapidity diminishes constantly, and a momentary interruption suffices to determine an augmentation of the current.

Whilst under a constant pressure, the current is established without interruption. On comparing the quantities delivered during two minutes (*e.g.* from the lungs), it happens that the second is larger than the first; there are oscillations such that the rapidity rises, diminishes, rises again and diminishes, until it falls more and more towards zero. In a dead organ the rapidity does not undergo the same oscillations as in a fresh one; in a dead organ (*e.g.* lungs, twenty-four hours after death) the rapidity, at first constant, abates gradually and progressively; there are no oscillations of the current; the quantity obtained during one minute is equal or inferior, without recurrence, to that obtained during the preceding minute. Œdema, although it does contribute to lessening the rapidity of the current, is equally, with the idea of capillary embola, incapable of explaining the oscillations observed. The changes undergone by the blood after its passage through excised organs, *e.g.* muscle, lungs, etc., have already been studied by J. J. Müller, Ludwig, A. Schmidt, and Genersich. In experiments on excised lungs the author finds that, all other circumstances being equal, the rapidity of the blood-current traversing the lungs is proportional to the pressure exerted in the pulmonary artery. With the same pressure in the pulmonary artery the quantity of blood which traverses the lungs is much greater when they are dilated by the pleural cavity. With the same pressure in the pulmonary artery, the quantity of blood which flows through the lungs is much less when they are dilated by inflation through the trachea. The blood is attracted to the pulmonary vessels during inspiration.

Circulation in the Excised Liver.—The author points out that the oscillations in the current are again found in the liver, where the vena portæ in its ultimate ramifications contains no muscular fibres, but only connective tissue and elastic fibres. The following, the results of Belz's experiments under Ludwig, on the circulation of a solution of gum in the liver, are then stated; and as they are not generally known they may be introduced here. In taking into view the diameter of the hepatic artery and that of the vena portæ, the portal circulation has a greater rapidity than the arterial hepatic one. The circulation in the hepatic artery is facilitated by the absence of a current in the portal vein; it is interfered with by a simultaneous current. The retention of bile in the biliary canals is a serious obstacle to the circulation of blood in the portal vein. If two different pressures succeed each other, the current varies, not only with the pressure under which it penetrates, but also with that which precedes it. If at the beginning of a current

the pressure be constant, the quantity of fluid which passes through the liver is at first variable, and it is only after about ten minutes that equal quantities are received from minute to minute. With the same pressure in the vena portæ, the rapidity diminishes proportionally to the pressure exercised on the surface of the liver. The immense importance of these observations, both clinically and practically, is at once obvious.

Influence of Toxic Agents on the Blood-current in Artificial Circulation.—If a few drops of an alkaloid be added to defibrinated blood, the current of blood which passes through the organ is immediately modified. Thus, nicotin added to defibrinated blood, circulating through excised lungs, greatly increases (to three times) the rapidity of the current. As soon as normal blood is admitted, the action of the alkaloid is effaced, the slowing of the rapidity (as expressed by the quantity which flows out from the pulmonary vein in a given time) which succeeds the toxic action is regular as in a dead organ; it shows no oscillations, yet a new dose of the alkaloid produces again an acceleration. The modifications in the rapidity are proportional to the dose of nicotin employed; the larger the dose, the greater the rapidity. Nicotin has, therefore, a special action, entirely opposite to that of cyanide of potassium, which causes arrest of the circulation by cedema.

Exactly the same is true of the liver.

In thus experimenting on excised organs we eliminate all effects of the central nervous system, to whose influence too many phenomena in the physiology of the circulation are too apt to be ascribed. Nicotin when added to blood produces a change in its colour and constitution; but this is not the cause of the action, for large doses of nicotin added to blood passed through dead organs had no influence whatever on the rapidity of the current. By the aid of Poisseuille's formula, it is shown that there are modifications in the calibre of capillaries under the influence of certain toxic substances, but whether due to contractility proper or not, the author leaves undecided.

WM. STIRLING, D.Sc., M.B., Edin.

WARLOMONT ON THE CASE OF LOUISE LATEAU, THE MYSTIC OF BOIS D'HAINE.

(Continued from page 130.)

The commission having no doubt as to the genuineness of the ecstasies as manifested by Louise Lateau, and also of the spontaneous occurrence of the stigmatic hæmorrhages, proceed to remark in relation to the ecstasies, that there is a very widely diffused class of diseases supposed to have their seat in the nervous system, and named neuroses, some of which are classic and others of rare occurrence. A marked characteristic of one of the principal groups of these diseases is the faculty, in virtue of which the patient under its influence momentarily quits his physiological condition to enter into a secondary state, during which his acts, functions, and ideas differ essentially from what they are in the normal state; the brain, limited in its action, either no longer perceives external stimulants, or no longer interprets them in the usual way. In fact, life is duplicated. This duplication of life is not only one of the multiform manifestations of the innumerable varieties of idiopathic neuropathies, it may also be produced under other conditions, viz., after

material lesions of the brain; during the existence of well ascertained neuroses, and under the influence of certain special processes, as hypnotism, magnetism, etc.; and spontaneously, without the intervention of any external provocation, as in somnambulism, extraordinary neurosis, etc. The report enlarges successively on each of these various states. As an instance of the first, it cites the interesting account of Sergeant F., lately published by Dr. Mesnet (*On Automatism, Memory and Recollection in Pathological Somnambulism*, in the *Union Médicale*, 1874, nos. 87 and 88) and another case by the same writer (*Studies on Somnambulism*, considered from the Pathological Point of View, in the *Archives Générales de Médecine*, 1860). It concerns a woman who, in the course of an hysterical affection, was attacked in the night with mimetic ecstasy and somnambulism, during which she gave herself up to the most singular actions. The third of these states relates to the duplication of life as it is observed in hypnotism and magnetism, those varieties of artificial nervous sleep which have been so often and so long misinterpreted, that medical men have thought it better not to trouble themselves any more about their legitimate interpretation. This is a mistake. There is something in hypnotism and animal magnetism, and the profession should have the courage to search for this entity. It is necessary to recognise that, by whatever name it is called, there is a power capable of developing itself either spontaneously or by extremely simple means, and which it belongs to our epoch to define, by means of which a human being may be momentarily brought into the state of secondary condition. It is sufficient with a certain number of patients, to make them look for a certain time, from ten minutes to half-an-hour, at a shining object, situated at some distance from the eyes, before and slightly above, so as to keep them in a convergent condition (hypnotism). A mental condition is then produced, of which MM. Demarquay and Giraud-Teulon have placed the seat—hypnotising aura—in the cerebral regions where the optic nerves and the common oculo-motor end; that is, in the small space of the encephalic mass comprehended between the cerebral peduncles and the quadrigeminal tubercles. The magnetic passes really act in the same way; the eyes of the magnetiser or the fingers passed before the eyes, performing the office of the shining object; the same effect, fatiguing or congestive, is produced.

The author reports a remarkable fact of secondary condition produced by magnetic passes in a blind patient. A lady, during two years and a half, found herself in the curious position of not being able either to eat or drink except when her physician had magnetised her. He was obliged to visit her twice a day to make her take her meals, and, if circumstances caused him to absent himself for one or many days, his patient accompanied him. Directly she was asleep she ate and drank, and when she was awake was utterly unconscious of what had passed. This state, said the reporter, lasted for two years and a half, and if she had not been told of these remarkable occurrences, she would have sworn by all that she held sacred that she had neither eaten nor drank during that long period. In connection with these facts, there are others in which the duplication of life is spontaneously produced, of which the report cites numerous examples. The reporter brings into prominence the striking analogy which connects these diverse manifestations with those of the

pathological group termed neuroses. He remarks that both are undoubtedly the result of perturbations of the cerebro-spinal nervous system, localised, in all probability, for the different varieties of nervous sleep, in the cerebral region, situated between the cerebral peduncles and the quadrigeminal tubercles. This point settled, *quid* the ecstasies? By comparing them with the facts cited, it is seen that there is not one of these symptoms which is not represented in one or the other class of neuroses, and their right to be placed in the class of neuroses cannot be the subject of a doubt. On the other hand, their similarity with nervous sleep, from this point of view of duplication of life, allows their seat to be fixed in the same part of the cephalo-rachidian bulb.

The stigmata now call for consideration; and all writers have explained them by the influence of the mind on the body. The report is based on this action, which it demonstrated by a large number of facts, amongst which the following demands attention.

A distinguished physician of Antwerp writes to the commission: 'I can produce in every part of my body and at every moment of the day, by my will, a more or less intense pain. As to the facility of production, according to the different points of the body or articulations, the pain irradiates the whole of the lower part of the limb. In the vertebral column, that which is evoked in the nape of the neck spreads throughout the head; that of the back brings on a constriction of the chest; that of the loins, pain in the abdomen. But the phenomena are most strongly marked in the palms of the hands; in all other parts the pain disappears as soon as the desire to produce it is at an end; but there the pain persists for a long period, and even becomes very acute, and I can only make it cease by the aid of some powerful distraction; the cause of this, no doubt, is, that I have the most frequently solicited it at that part.'

The question may be fairly asked, if this pain really have its seat in the locality mentioned, or, if it be not the brain by which it is really produced. The answer written by the same person is, that another phenomenon showed itself on December 31 last, during the time that he made the pain persist in a given locality; the pulsation of the arteries was sensibly augmented. Thus the effect produced on the circulation of one part of the body, when the attention is abruptly directed towards it, is sometimes locally appreciable, and innervation as well as circulation undergo a special over-excitement, whence an increase of the functional activity of that region is induced. To think only of one's self, to concentrate all the powers of one's mind on some one portion of the body, is to provoke an excitement of that portion of the sensorium, or of the nervous system, which regulates that part. The general result is disturbance in the action of that part, consisting in a relaxation of vaso-motor stimulus, with local congestion of the vessels. The question arises, whether the stigmata seen on Louise Lateau answer to this description. It must be borne in mind that she always had the desire to suffer; and that this desire increased from the day when 'she received that internal light which made her understand that something extraordinary was passing within her; that from that time forward she began to feel in her body the painful sensations of those stigmata which she was soon about to receive.' Here, then, were the pains, the precursors of the stigmatisation. *Ubi stimulus, ibi affluxus.* The congestion soon

follows, and the cause which set this congestion in motion is quite perceptible. Do we not every day see persons feeling any kind of pain constantly putting their hand to the region where it is situated, notwithstanding the warnings and advice of the doctor? Louise was not able to avoid this temptation. In all probability she, without any bad intention, put her hand frequently on the painful spots, irritated and rubbed them, and in that way induced a more considerable afflux of blood. Thus a perfect chain of circumstances explaining the formation of the stigmata is formed:—The mental act evolving pain by a determinate cerebral action; congestion created by that pain, urged on by external excitations; consecutive loss of elasticity in the capillaries of the congested parts; stasis of the blood in the capillaries; dilatation of those vessels; angioma. This view of the case is not merely hypothetical, for it has been fully confirmed by microscopical examination made of a morsel taken from the depth of the dorsal stigmata of one of Louise's hands whilst she was in a state of ecstasy. This small fragment, examined by M.M. Crocq and Warlomont, showed intertwined bundles of connective tissue, dilated vessels of which the smallest measured five hundredths of a millimètre, and a papilla with a vascular loop of twenty-eight thousandths of a millimètre. Now, according to Kölliker, the capillaries of the papillæ measure at the maximum eight thousandths of a millimètre, and those of the superficial layer from ten to twenty thousandths. In Louise Lateau, these vessels, especially the former, had, therefore, undergone a considerable enlargement. M. Warlomont points out that Dr. Richardson, in a paper on purpura, published in the *Lancet* for November 28, 1874, gives the physiological explanation of the stigmata in relation to a patient suffering from that disease who had been under his care, and shows that the conditions favouring the production of the phenomena are, aglobulia of the blood with predominance of the serous element, and a limited change in the capillaries of the affected region; two fundamental conditions which were met with in Louise Lateau. He says, 'At certain points a slight subcutaneous swelling is set up, to which the name of aneurism of an arteriole or of the capillaries may be given.' M. Duwez, who assisted M. Warlomont in his investigation, had arrived at the same conclusion before these articles appeared, and had applied the name of angioma to the stigmatic processes in the case of Louise Lateau. The angiomata became converted into bleeding stigmata in this way. When the paroxysms characterised by this molimen hæmorrhagicum and the consequent local congestive breakings-out come on, the leucocytes will pass through the capillaries, become effused under the epidermis, and a blister ensues. The accumulation of blood continuing in proportion to the dilatation of these capillaries, the epidermic covering will finally break up. Then the blood itself, passing through either the passage created by the anterior passage of the leucocytes or through vascular ruptures of plausible probability, will make its way outwards. Hence the hæmorrhage, which will last as long as the cerebral excitement which gave rise to the attack which kept it up.

After lengthened consideration of the anatomopathological conditions, M. Warlomont refers the cause of these phenomena to a disturbance of the principal vaso-motor centre, situated in a space comprised within the limits of one millimètre behind the

quadrigeminal tubercles and from four to five millimètres in front of the lower extremity of the calamus. This region corresponds precisely with that in which the hypnotising aura is found, already designated by him as the starting-point of the ecstasies; he thence concludes that the ecstasies and the stigmata in conjunction constitute a combination to which he proposes to give the name of stigmatic neuropathy. He adds that the neuro-stigmatic combination is not the only one of its kind. Palpitations of the heart, exophthalmos, and goitre have long been known as isolated symptoms, and special entities possessing an absolutely independent genesis. Who, then, could have imagined that a day would arrive when these three morbid manifestations would be found united in the same person, under the influence of a common cause? This, however, has now come to pass in the case of Louise Lateau, and it is caused by a neurosis of the great sympathetic.

In an appendix to the report, M. Warlomont specially treats the question of abstinence, and he lays down the following propositions containing the opinions of the commission on the occurrences at Bois d'Haine.

1. The two expressions—relating to M. Virchow's dilemma, used by that investigator—cheat or miracle, should be put on one side. These stigmata and ecstasies are real, and are explained by physiology.

2. The phenomena displayed by Louise Lateau constitute a disease of the neurotic order. It may be conveniently classed in the nosological list, under the name of stigmatic neuropathy.

3. Louise Lateau works and expends caloric; every Friday she loses a certain quantity of blood by the stigmata; the gases expired by her contain watery vapour and carbonic acid; her weight has scarcely varied at all since she has been under observation; therefore she burns carbon which she does not derive from her own organism. Whence, then, does she obtain it? The answer made by physiology is that she takes food.

4. The abstinence of Louise Lateau, as affirmed, is contrary to the laws of physiology, and, consequently, there is no need to prove that it is a fabrication. As it is established that this fact is beyond those laws, it is for those who affirm it to demonstrate its truth. Until then, physiology must hold it to be an apocryphal statement.

ANATOMY AND PHYSIOLOGY.

HARNACK ON THE ACTION OF APOMORPHIA ON MAMMALS AND THE FROG.—E. Harnack (*Archiv für experiment. Pathol. und Pharmac.*, 1874, vol. ii., from the abstract in *Centralblatt für die Med. Wissensch.*, no. ii. 1875) says that, from the previous investigations on the action of apomorphia, it was believed that in this substance we possessed an emetic which, apart from its emetic action, did not exercise any important secondary effects on the organism. From the author's experiments, however, it appears that this substance acts on certain parts of certain animals in a very intense and deleterious manner.

To exclude the act of vomiting, and to obtain as clear a view as possible of the secondary effects of the drug, the author experimented on rabbits, which do not possess the faculty of vomiting. It was shown that

even 10 to 30 milligrammes (0.15 gr. to 0.45 gr.) of apomorphin produce death in the rabbit, whilst 5 to 10 milligrammes (0.075 to 0.15 gr.) are sufficient to produce important changes in certain bodily functions. The smaller doses threw the animals into a state of the highest excitement and uneasiness; they ran to and fro in the room, crawled into dark corners, and were very frightened. In addition, in most of them there was salivation. This condition ceased after a few hours, and the animals returned to the normal. If the doses employed were greater, unsteadiness of gait soon set in, the posterior extremities being first affected; the animals suddenly fell over in convulsions, the respiration ceased, and death occurred, and could not be averted by artificial respiration.

The frequency of the respiration was at first enormously increased, and, according to the author, this increase is to be ascribed to stimulation of the respiratory centre, and it occurs even after division of the vagi. This stimulation was followed by a diminution of the excitability, and ultimately by paralysis of the centre.

As to the question whether the convulsions are simply the consequence of the disturbance of the respiration, or are dependent on stimulation of certain central organs, the author seeks to decide by experiments on chloralised animals. These experiments showed, first, that in such animals, convulsions are absent; and secondly, that animals narcotised with chloral can bear much larger doses of apomorphia, and that death is accelerated by the occurrence of convulsions. The absence of convulsions, the author seeks to ascribe to the paralysis by chloral of those central organs, upon whose stimulation by apomorphia the convulsions depend; he assumes a direct stimulation of the central organs, and so it appears to him possible that, conversely, there would be difficulties in diminishing the activity or paralysing by narcosis the motor centres stimulated by apomorphia.

The author then touches the question as to the identity of the vomiting and respiratory centres, and, from experiments on narcotised dogs, decides against this view. He says, 'Proceeding on the assumption of the identity of the respiratory and vomiting centres, one must expect that in such narcosis apomorphia is able without hindrance to produce vomiting, in that, the respiratory centre has not lost its excitability; and we have seen in rabbits, that in this condition the centre undergoes a powerful stimulation by apomorphia. One cannot, however, produce vomiting during the narcotic condition.'

In the frog the author observed first a stimulation, and then a complete paralysis of the centre of voluntary movement; later the irritability of the transversely striped muscles is diminished, and with large doses completely paralysed, without their becoming rigid. This paralytic action on transversely striped muscles apomorphia possesses in common with several other emetic substances, e.g. emetin, tartar emetic, cyclamin, and asclepiadin, a substance which, in its action, according to Harnack, is analogous to apomorphin.

Lastly, the author attempts to establish, experimentally, in what way the increase in the frequency of the pulse accompanying vomiting arises; whether it owes its origin to a diminution in the tonus of the vagus, or is due to stimulation of the accelerating apparatus of the heart. Supported by the fact that stimulation of the accelerating nerves produces in-

crease of the frequency of the pulse without increase of the blood-pressure—that, on the contrary, diminution of the tonus of the vagus is accompanied by increase of blood-pressure—the author observed the pulse and blood-pressure after injection of apomorphia into dogs, and found that increase in the frequency of the pulse produced by the act of vomiting is not accompanied by an increase of the blood-pressure; therefore, that the relations existing during the act of vomiting are analogous to those which are produced by artificial stimulation of the accelerating nerves.

HEIDENHAIN ON THE SALIVARY GLANDS.—R. Heidenhain (*Pflüger's Archiv*, vol. ix. and abstract in *Centralblatt für die Medicin. Wissenschaften*, no. 1, 1875) says that Rossbach questioned the antagonistic action between atropin and physostigmin in relation to the secretory fibres of the chorda tympani, as asserted by Heidenhain. To establish his results, Heidenhain atropinised curarised dogs by injection into the blood, until stimulation of both chordæ no longer produced secretion, ligatured both subclavian arteries to control the circulation in the submaxillary glands, and injected a solution of physostigmin under previous occlusion of the carotid into the branch of the submental artery going to the hilus of the gland. The immediate consequence was that, on the side where physostigmin was employed, the chorda became again excitable, whilst stimulation of the other chorda gave no result, when, in order to make the conditions of the experiment alike in the two glands, a solution of an indifferent salt was injected into the artery of the other gland.

Gianuzzi showed in 1865 that, when the salivary secretion was arrested by the injection of dilute acid or solution of soda into the excretory duct, stimulation of the chorda tympani produced a very considerable œdema; and he concluded from this that the secretion normally consists of two acts, of the increased transudation of lymph by paralysis of the vessels, and of the formation of saliva from this material by stimulation of the secretory nerves. Heidenhain shows that this hypothesis is untenable, in that, after the injection of atropin into the gland, stimulation of the chorda caused acceleration of the blood-current, but never pronounced œdematous swelling. The latter is also absent on injecting an indifferent fluid into the excretory duct after atropinising, but occurs at once when a dilute acid or soda solution is used instead of the indifferent fluid. The author suggests that the œdema arises from diffusion, caused by the differences of the blood-fluids and the acid or soda solution injected bathing the vessels.

BLAKE ON THE USE OF THE MEMBRANA TYMPANI AS A PHONAUTOGRAPH.—An interesting series of acoustic experiments have been carried on in the United States during the past year, by Dr. Clarence Blake and Professor Graham Bell (*Boston Medical and Surgical Journal*). Some of the results were recently brought before the Boston Society for the Advancement of Medical Science, but a fuller report is promised shortly.

A remarkable feature of the experiments was the apparatus employed, viz., the human membrana tympani, with the ossicula; it was adapted to the purpose as follows. A specimen, as nearly normal as possible, was obtained; the temporal bone was removed and carefully cleaned, and the lining of the external auditory canal cut away to a line close to the mem-

brana tympani. The thin plate of bone forming the roof of the tympanic cavity was then cut away by means of a bone-chisel, great care being necessary to avoid disturbing the ossicula. The articulation between the incus and stapes was next divided by means of a narrow-bladed knife, and the tendon of the tensor tympani muscle either cut across close to its insertion into the malleus, or else left for experiment. A section was then made with a hair-saw through the tympanic cavity from behind forwards, separating the petrous from the mastoid and squamous portions of the temporal bone, the section being carried between the incus and stapes. Great care is necessary in this part of the operation, for the slightest touch of the saw on the incus will so derange the relations of the ossicula as to render the specimen useless for experimental purposes. The inner surface of the membrana tympani is thus exposed with the malleus and incus in position; this is carefully cleansed from bone-dust, and must be kept moist with glycerine and water. A bell-shaped mouth-piece is then fixed into the external auditory meatus, and the whole screwed to a stage plate opposite a carrier which is moved by a weight attached to a cord passing over a pulley at one end of the stage. A style, made of a fine fibre of split straw is glued to the descending process of the malleus or incus; a slip of smoked glass is placed on the carrier; a note is sounded in the bell-mouth and the weight let go. As the glass travels past the end of the style, a wave-line, corresponding to the character and pitch of the musical tone, is traced upon the smoked glass.

Not only does the human ear, when thus prepared, make a most delicate phonograph and logograph, but some interesting researches have been made into the acoustic properties of the membrana tympani itself.

J. W. LANGMORE, M.D.

RABUTEAU ON THE DAILY EXCRETION OF URINE IN HEALTH.—In the *Gazette Médicale de Paris*, for Jan. 30, 1875, Dr A. Rabuteau publishes a series of experimental observations, instituted to determine the quantity of urine daily excreted by persons in health, in continuation of some others which he put forth in a note to the Société de Biologie in 1869.

In his present paper Dr. Rabuteau affirms the commonly received opinion, that a larger quantity of urine is eliminated in winter than in summer, to be founded on mere presumption; and maintains that really it is only in those individuals who drink without being thirsty, or who abuse alcoholic liquors, that the winter average seems to be greater. If persons in health preserve a fairly uniform diet, and drink only when thirsty, their daily excretion of urine is pretty constant.

The author gives a table of mean results, deduced from observations made with more or less regularity from Dec. 1867 to April 1870; from which he cites two examples to show that the smallest mean quantity (877 grammes) was observed during the very hot weather of July 1868; while a nearly identical result (880 grammes) was obtained during the very cold weather of March 1869. The highest mean quantity (1,037 grammes) is recorded for June 1868; but the temperature of the month is not mentioned.

Taking all circumstances into consideration, the author considers that the average quantity of urine excreted by persons in health is 1,200 grammes, or approximately, 1,175 cubic centimètres (about forty-

two ounces) in twenty-four hours ; and further, that the daily amount increases with age.

BUSHELL ANNINGSOON, Cambridge.

GALIPPE ON THE ACTION OF JABORANDI BARK. Galippe and Rochefontaine (*Progrès Médical*, February 13, 1875) state that infusions of jaborandi bark produce the same physiological effects as infusions of the leaves. Among those effects, they enumerate diarrhoea and marked dilatation [contraction? *Rép.*] of the pupils.

GALIPPE ON ABSORPTION OF CANTHARIDINE.—To prove that cantharidine is taken up by the blood in considerable quantity, the following experiment was performed (*Gaz. Médicale de Paris*, February 8, 1875). A dog was poisoned with five centigrammes of cantharidine, administered in the form of a pill. After the specific effects of the drug had shown themselves, the femoral artery of the poisoned animal was connected with that of a healthy dog, and transfusion was allowed to go on for several minutes. The second dog presented the symptoms and *post mortem* appearances characteristic of the poison.

PATHOLOGY.

MONOD ON NON-CARCINOMATOUS TUMOURS OF THE BREAST.—In a very interesting contribution to the study of non-carcinomatous tumours of the breast, by Dr. Charles Monod,* published in the *Archives Générales de Médecine*, January, 1875, in order to contrast non-carcinomatous with carcinomatous tumours of the breast, the author first succinctly describes the anatomical peculiarities of the latter, insisting on this point—the gland, its constituent elements, acini, and excretory ducts, disappear as the carcinomatous tissue develops. Quite otherwise, he proceeds to say, is the physiognomy of the non-carcinomatous tumours ; here the characteristic tissue of the gland persists, distorted though it may be. This persistence, he thinks, explains the confusion of tumours made by many authors under the name of adenoma.

The object of his communication is to show that the anatomical peculiarity of these tumours is not to be sought in the glandular element, always more or less well preserved, but in the intermediate tissue ; and that only by a careful analysis of this tissue can their exact nature be defined.

He acknowledges that this view of the matter is not new, but thinks, from the tenor of recent discussions, that it may be useful to bring it again before the public, and to state the results of his own personal researches.

He refers to the naked-eye appearances of

non-carcinomatous tumours which present some anatomical features in common. 'It has been completely demonstrated that these cavities' (which he had just described as visible in a tumour by the unaided eye) 'are nothing but the glandular cavities of the breast, abnormally developed and deformed by the pathological tissue which has arisen in the gland. They have been described by M. Ranvier under the name of *kystes lacunaires*, to distinguish them from the true cysts which are met with in the breast. These cavities all present a perfectly smooth surface, which may be easily shown, microscopically, to be lined with epithelium,' by the process of staining by nitrate of silver. This epithelium is also to be seen in sections made after hardening.

He points out that microscopical examination of scrapings only is insufficient, as the elements of the tissue intermediate to the *culs-de-sac* must often escape attention. For a complete anatomical diagnosis, it is insisted that the examination of the separate elements must be followed by a study of their reciprocal arrangement.

He goes on to describe the relation which may be seen to subsist between the cavities, ducts, and epithelial surfaces in the tumours. 'The presence of the epithelium is the only point in common between them. But it is not in the glandular element that the characters necessary for distinguishing the different tumours of the breast must be sought. These distinctive characters are only to be found in the stroma between the acini and the dilated excretory ducts, in the tissue which constitutes the walls of the cavities, or the growths into their interior.' 'This tissue, in the preparations which we have examined, shows itself sometimes with characters of well formed fibrous tissue, or, more often, young tissue abundantly provided with cellular elements ; sometimes showing in all points the appearance which sarcoma and myxomata develop in other parts of the body.' 'We do not lay stress on the histological differences which separate these three varieties of pathological tissue. In some cases difficulty is experienced in distinguishing them from one another.' 'If we are right in the way we have understood the constitution of the tumours we are studying, it is evident that they must be distinguished and consequently named from the nature of their stromata.' 'In short they must be considered as fibromata, sarcomata, or myxomata of the breast, and not as adenomata more or less transformed.' 'Yet it does not follow that the idea of a concomitant glandular hypertrophy must be absolutely set aside.' 'The increase in the number of acini is possible and even probable. Indeed, if on the one hand, we consider the slight proportion of glandular element in the virgin breast, and, on the other hand, the great number of dilated and deformed acini met with in the small fibrous tumours of the organ developed in the same circumstances, we are forced to admit that a hypertrophic action propagated in the gland has accompanied the neoplastic formation in the intermediate stroma.

'In favour of this view, the argument of MM. Cornil and Ranvier (*Manuel d'Histologie Pathologique*) may be cited. It is based on the examination of tumours of this class, recurring after ablation. The tumour no longer contains gland structure ; an evident proof that in the original tumour the glandular hypertrophy constituted only an accessory element.' 'Non-carcinomatous tumours of the breast appear generally

* Chef du Laboratoire de l'Hôpital des Cliniques.

under two principal forms; one, commonly small and exhibiting few, if any, true cyst-cavities; and a second, in which the cystic dilatations are often of considerable diameter (cysto-sarcoma); its size is ordinarily voluminous, and it is accompanied sooner or later by ulceration and even perforation of skin and protrusion of growth. The first form ordinarily behaves like fibroma of the breast, sometimes, however, like a sarcoma. This last fact explains the relapse of tumours apparently benign, or their suddenly rapid increase, or again their apparent transformation into cancer. 'The two forms, however, belong to the same fundamental type, and constitute a natural group of tumours, which should anatomically and clinically be separated from carcinoma.'

Next, the author gives an interesting though brief retrospect of the diverse phases of the history of these tumours from the time of Astley Cooper. This writer divided benign tumours into two classes; the first, which he termed hydatid disease, comprised different varieties of cysts of the breast; chronic mammary tumours constituted the second class.

'A. Cooper did not perceive the relation which existed between these two groups, so different in appearance. It could not be otherwise, from the insufficient means of examining these tumours at his disposal. The intervention of the microscope did not at first seem to throw much light on the question. It, however, enabled John Müller to establish the group of cysto-sarcoma phyllodes,' which is characterised by projections and numerous vegetations penetrating into the cavity of the tumour. J. Müller thus confirmed the idea already enunciated by A. Cooper, that there might be developed in the breast, tumours, quite distinct from cancer, constituted by a particular neoplastic tissue, distinct equally from simple, partial, or total hypertrophy of the mamma. However, Müller made the mistake of not studying the growths described by Cooper under the head of chronic mammary tumour.

Lebert, Velpeau, Robin, and Broca fell into the opposite error in only seeing in non-cancerous growths normal gland-elements without true neoplasia. The names which they gave to these tumours clearly indicate the idea which they had of their nature—partial hypertrophy of the mamma (Lebert), adenoid tumours (Velpeau), adenoma (Broca). Had these authors studied the changes in the interacinary tissue of the gland, they would then have distinguished in the group of tumours which they designate adenoma, varieties corresponding to clinical experiences; they would soon have remarked that, in fact, these tumours, reputed benign, were far from deserving all the same prognosis. Busch, in Germany, demonstrated that the clefts or lacunæ seen in fresh sections were in communication with the gland-ducts. He inserted a fine probe in one of the galactophorous ducts near the nipple, and followed it into the cystic spaces, great and small, of the tumour. Baur later arrived by the same means to the same conclusion.

Passing over the works of Birkett, Paget, Mettenheimer, Schuh, Rokitansky, and Reinhardt, the author quotes from a communication of M. Verneuil to the 'Anatomical Society,' where he described a tumour which preserved the glandular appearance, but presented fibro-plastic tissue in its walls. 'Trusting to the form only, the surgeon might believe he had to do with a hypertrophic tumour only, when in reality he had to deal with a fibro-plastic growth most

subject to relapses.' Billroth's memoir on non-cancerous tumours of the breast is mentioned as a remarkable work. He gave these growths the name of adenoid sarcoma to distinguish them from the fibrous, gelatinous, encephaloid, and medullary sarcomata. The author remarks that the qualification adenoid simply denotes the place where the neoplasm has developed, and thinks that the distinction drawn by Billroth was illusory. 'The fundamental idea of Billroth's work was, however, right.' This opinion has for a long time been maintained by M. Ranvier, in several communications made to the 'Anatomical Society,' and recapitulated by him in his *Manuel*. It was he above all who, in France, opposed the old conception of adenomata, according to Lebert and others. Virchow at the same time, in Germany, arrived by another route to analogous conclusions. In the *Traité des Tumeurs*, as in the work by MM. Cornil and Ranvier, it is not a question of adenoid tumours or adeno-sarcomata of the breast, but solely of sarcomata, fibromata, and myxomata of the mamma, of which the study constitutes no more than a particular one of general sarcomata, fibromata, and myxomata.

Lastly he briefly mentions the works of M. von Wyss,* who follows the views of Billroth and Virchow, and the work of M. Cadiat,† who accepts the ideas of Velpeau and Lebert, and is therefore of opinions opposed to the author. JOHN CROFT.

MEDICINE.

LORAIN ON CASES OF SUDDEN EMOTIONS IN WOMEN PRODUCING PERSISTENT NEUROSES, SUCH AS HYSTERIA, CHLOROSIS, CHOREA, AND PARALYSIS AGITANS.—M. Lorain, after noticing the popular tendency to argue on the *post hoc ergo propter hoc* principle in nearly every disease, asserts that this tendency has caused medical men in many cases to treat such accounts with scepticism. 'We have good reason,' he says, 'to reject these too facile explanations; but should we therefore always refuse them, in a spirit of routine, or should we sometimes admit them, and to what extent?'

With a view to the settlement of these questions, he submits to notice the following reflections on cases which have occurred in his own experience. In each of these cases there has been some sudden emotion followed by neuroses, which have persisted for a greater or less period.

Other considerations arise from the study of these cases. Among these are the following. Does the accident decide the seat of the morbid manifestations which follow it? Have such accidents corresponding morbid conditions? Is it right to call a woman hysterical who suffers from hemiplegia, or who falls into a state of clonic convulsions with globus hystericus and other morbid sensations?

Shall a woman, however, who becomes after a similar accident choreic, be excluded from the ranks of hysterical patients because of her chorea?

Is it also necessary to make a separate class for chlorotic patients?

The author protests against such exclusiveness,

* Hans Von Wyss, 'Beitrag zur Kenntniss der Brustdrüsen Geschwulste,' Inaug. Diss., Zurich, 1871.

† Cadiat, 'Du Développement des Tumeurs cystiques du Sein,' *Journal de Robin*, 1874. No. 2, p. 183, 2 pl.

and proposes that all the cases of neuroses occurring in women after sudden accidents should be included in one term, *Feminisme*.

Among the observations recorded are the following. Two girls suffered from chorea following fright. At the time of the accident they were menstruating, and in consequence of it the discharge was immediately arrested. In one the chorea is combined with rheumatic symptoms; in the other there are so many undoubted hysterical symptoms that she must be classed among the hysterical patients. [Is it not probable that the latter of these two patients has imitated the choreic symptoms of the former? They are reported to have been in the same ward.]

In another case, a girl, aged fifteen, who had been ailing and out of sorts for some time, was startled during menstruation by a flash of lightning, which struck the ground about thirty yards from her. The catamenia were arrested after having lasted for but a small portion of the time it generally did. The next day she was attacked with chorea which became very severe.

Another girl, aged twenty, after the bite of a horse, was seized with hysterical convulsions, which were followed by loss of cuticular sensibility, and ataxic symptoms. In another case of a girl, aged twenty, after the receipt of some bad news, hysterical paralysis occurred.

The last case related is that of a girl, aged seventeen, who was attacked by paralysis agitans, after having been frightened during the siege of Paris, by the explosion of a shell which killed several people who were standing near her.

W. KESTEVEN, JUN.

MEIGS ON PNEUMO-HYDRO-PERICARDITIS.—An example of this very rare cardiac lesion is recorded by Dr. Meigs in the *American Journal of the Medical Sciences* for January. The patient was a delicate young man, eighteen years of age, of tubercular diathesis and with a strong family predisposition to rheumatism. As the result of exposure to cold and wet he was attacked with pleurisy, first on the right and then also on the left side; this gave rise to no great amount of effusion, but was accompanied by high fever, much pain, and rapid prostration; there was no renal disease. At the end of three weeks cardiac friction appeared, and then signs of effusion into the pericardium. A few days later, just a month after the commencement of the illness, Dr. Meigs on approaching the patient, heard, at a distance of some feet from the bed, a peculiar splashing noise like the working of a churn. On listening over the præcordium the peculiar splashing sound was heard to recur with each stroke of the heart; the heart-sounds had an extraordinary reverberating amphoric character; metallic tinkling was also heard; the percussion-note over the cardiac region was found to be tympanic. The facts that the resonance was confined to the middle portion of the chest, and that the succussion-sound was precisely synchronous with the heart's action, left no doubt that there was air or gas, as well as fluid, in the pericardium. The stomach was not much distended; there had been no signs of any pulmonary cavity; and the existence of vesicular breathing all round negated pneumo-thorax.

The patient died three days afterwards, and the *post mortem* examination was made with most exemplary care and patience. On removing the whole contents

of the thorax and inflating the lungs through the trachea, no air entered the pericardium, but, on opening the œsophagus from behind, a depression about half an inch in diameter was seen on its anterior wall just below the bifurcation of the trachea. In the centre of this hollow was a small perforation, with ragged, dark, ulcerated edges, which communicated obliquely with the apex of the pericardial sac; the opening was just large enough to admit the point of a full-sized catheter. There had evidently been a partial spontaneous evacuation of the pericardial effusion by way of the œsophagus.

Dr. Meigs, in commenting on this case, gives references to all the similar cases he can find; there seems to be only about a dozen on record.

DA COSTA ON CEREBRAL RHEUMATISM.—The *American Journal of the Medical Sciences* for January contains a paper on this subject by Dr. J. M. Da Costa, professor of medicine at the Jefferson Medical College. The name cerebral rheumatism owes its origin to an hypothesis long disproved, viz., that the occurrence of restlessness and delirium in acute rheumatism was due to actual inflammation of the membranes of the brain—to 'rheumatic meningitis.' Meningitis may occur under these circumstances, but it is a rare complication, and in the great majority of the cases of cerebral rheumatism there is no meningeal lesion whatever. Still the name has acquired a definite signification as regards the class of cases which are included under it, and it is therefore convenient to use it.

Recently the association of these brain-symptoms with high temperature has been noticed, and 'hyperpyrexia' has been supposed to be the cause of the delirium; but Dr. Da Costa says that in many cases of cerebral rheumatism the temperature is not very high, and he relates a remarkable case in which, though a temperature of 110° was attained, there was an entire absence of cerebral symptoms. No artificial cooling or special treatment of any kind was employed, and the patient recovered. Dr. Da Costa is inclined to refer the brain-symptoms partly to the circulation of vitiated blood, and partly to disturbance of the cerebral circulation consequent on the plugging of numerous small arteries by fine emboli. These may be formed in the heart, but more often originate in the arteries—thromboses: he relates some cases in which this state of things was verified *post mortem*. The possible existence of uræmia must not be forgotten as an occasional cause of similar symptoms. Dr. Da Costa states, however, that the literature of cerebral rheumatism is not yet as complete as the importance of the symptoms seems to deserve, and that much clinical work has yet to be done before the subject can be said to be fully elucidated.

HOOD ON CARDIAC WEAKNESS AS A REMOTE CONSEQUENCE OF INJURIES BY RAILWAY COLLISIONS AND OTHER ACCIDENTS.—Dr. Hood calls attention (*Lancet*, February 27) to the value of a careful examination of the pulse and of the action of the heart as an aid to the diagnosis of the notoriously difficult class of cases referred to above. He states that in a *bonâ fide* case of injury from railway collision, along with the common evidences of nervous depression, symptoms of an hysterical character, there will frequently be found a weak cardiac impulse, and a feeble, or even intermittent pulse. The patient may look well, but is generally

pale, and is disinclined for, or incapable of any exertion, either mental or bodily.

Dr. Hood advocates blood-letting after a railway accident, not indeed immediately, but as soon as reaction has been established. The heart, he says, is partially paralysed; its action is weakened by the nervous shock, and by reducing the volume of fluid which it has to move, we may quickly enable it to carry on the circulation without distress. Without this assistance it may be long before the organ recovers its lost ground, or it may never regain it completely. He adds, 'It is well-known to those who are familiar with railway accidents and with military surgery, that those who have lost blood copiously do not suffer from the nervous depression so common among those who have sustained injuries unattended by hæmorrhage.'

J. W. LANGMÔRE, M.D.

BOUCHARDAT ON THE NERVOUS SYMPTOMS ASSOCIATED WITH DIABETES.—Bouchardat (*Bulletin Général de Thérapeutique*, February 28, 1875), enumerates the following: partial anæsthesia, hyperæsthesia, cramps, insomnia, lumbar pains, enfeeblement of memory and of the power of continuous mental application, drowsiness after meals, irascibility, and melancholy. The sleeplessness is really due to the incessant calls to pass urine, by which the patient is roused as soon as he begins to lose consciousness. The loss of memory is most apparent in persons who have passed middle age; the natural invasion of this mode of mental failure being accelerated tenfold. Indolence, apathy, and inaptitude for intellectual work are very usual symptoms. In common with all the other nervous troubles incidental to the glycosuric condition, they yield quickly to the influence of appropriate regimen and treatment.

E. BUCHANAN BAXTER, M.D.

FORENSIC MEDICINE.

WOODWARD ON THE DIAGNOSIS OF BLOOD-STAINS BY THE MICROSCOPE.—Dr. J. J. Woodward, United States army (*Monthly Microscopical Journal*, February, 1875), criticises the assertions made by Dr. J. Richardson, in a paper published in the *American Journal of the Medical Sciences*, July, 1874, as to the possibility of distinguishing human blood from that of certain other mammals, by direct measurement of the corpuscles, even in dried stains. These statements were criticised at the time of their appearance (*LONDON MEDICAL RECORD*, September 9, 1874), and Dr. Woodward shares, or feels even more strongly, the doubts and misgiving there expressed. He thinks it only fair to Dr. Richardson, to print a communication from him to the following effect. Dr. Richardson, it appears, was fully aware of the difficulty of making anything more than a differential diagnosis even in the cases he specified, and of the impossibility of distinguishing the blood of man from that of a monkey or dog; but he had refrained from giving prominence to these facts, lest an improper use should be made of them in the defence of criminals. Dr. Woodward, following the practice of many of the best writers on medical jurisprudence, entirely dissents from this view of the matter, and has no hesitation whatever as to his duty in speaking the whole truth on the subject.

Dr. Woodward points out that, though the aver-

age diameter of the red corpuscles of the dog and man, as given by Gulliver and Welcker, might seem to show a certain small but constant and measurable difference, still this is not borne out by an examination of the original essays of these authors, which show that extreme sizes, both smaller and larger than the average, are met with, and these differ so much as to make the average difference quite inapplicable. Thus Gulliver gives the average diameter of the human red corpuscle as $\frac{1}{3200}$ of an inch; but says that, in a single drop of blood, corpuscles may be found either a third larger or a third smaller than the mean size, or varying from $\frac{2400}{1}$ to $\frac{4800}{1}$ of an inch. Again, Gulliver gives $\frac{1}{3542}$ as the average size of the red blood-corpuscle in the dog; but also mentions $\frac{1}{4000}$ and $\frac{1}{3000}$ of an inch as common sizes. Hence, evidently no conclusion whatever can be drawn from the difference of the averages. Moreover, the absolute value of these results is diminished by the uncertainty as to the accuracy of any micrometer, and by disregarded variations produced by the correction of the object-glass; in fact, Gulliver himself only claims 'relative exactness' for his results. The measurements of Welcker give even less support than those of Gulliver to the notion that the blood of the dog can be distinguished from that of man by the microscope. His measurements as ordinarily quoted, give '00774 of a millimètre ($\frac{1}{3280}$ inch) for man, and '0073 (or $\frac{1}{3480}$ inch) for the dog; but the latter number was derived from observations on a single dog only; while in one case he found the blood of a healthy man to give a mean less than these, or '00724 millimètre, and the extreme measurements vary very considerably from the mean. The results of other observers, though they mostly give the average higher for human blood than for that of the dog, still show considerable variation, and one observer even makes the corpuscles of the dog larger.

Dr. Woodward's own observations show no constant difference between them. The mean of fifty corpuscles taken at random was seldom twice the same, and sometimes that of human blood, sometimes that of dog's blood, was a trifle the larger. He details with great minuteness the precautions taken in measuring specimens of human blood from five individuals, and dog's blood also from five individuals, not fewer than fifty corpuscles being measured in each specimen and the averages regularly taken. The size most frequently measured was equal in human and in dog's blood, viz., $\frac{1}{3333}$ of an inch; and the great majority of corpuscles varied in both cases from $\frac{1}{4167}$ to $\frac{1}{2941}$. The variations produced by drying appear to be extremely small; but this is of less consequence, as there could obviously be, to say the least, no greater certainty than in the case of fresh blood. The alterations produced by water are, on the other hand, considerable. The general result is, therefore, to confirm the accepted doctrine that the distinction of human blood by means of the microscope is not within the resources of science.

[We believe that most microscopists of experience will agree with Dr. Woodward, both as to the impossibility of the attempted distinction and the duty of the medical witness. We await Dr. Woodward's criticisms on the question of distinguishing the blood of sheep and oxen from that of man.—*Rep.*]

SURGERY.

MICHEL ON THE USE OF SULPHURET OF CARBON IN THE EXTERNAL TREATMENT OF CHRONIC ULCERATIONS.—In the *Journal de Thérapeutique* for Jan. 1875, p. 48, Dr. Evariste Michel relates his trials of sulphuret of carbon in M. Boys de Loury's wards, when Dr. Michel was his house surgeon at Saint-Lazare in 1867 and 1868. The results obtained were most beneficial. Sulphuret of carbon is used like the caustic liquids. In order to obtain the required effect, it is sufficient to touch the ulcerated tissues with a pledget of lint saturated with the liquid in the same way as with most acids. The frequency of the dressings depends on the degree of chronicity of the ulceration; a very old and inactive ulcer will require moistening every day, whilst less frequent applications, every two or three days, will suffice for a more recent and excitable ulcer. Sulphuret of carbon is not a caustic; and its contact with the mucous membrane does not leave any scar. Neither does it produce any discoloration except the amount resulting from its constant use, which characterises reparation of the skin. It gives acute but only instantaneous pain; and, whilst the suffering consecutive on a somewhat extensive cauterisation with acid nitrate of mercury sometimes lasts for many hours, it is rare that the pain due to the sulphuret of carbon is not entirely dissipated in a few minutes. This pain, which is somewhat intense on the first application, is less so at the second, and diminishes in proportion as the use of the dressing is prolonged, and as the cicatrising process becomes confirmed. M. Michel has never met with the smallest accident which could be attributed to the absorption of the sulphuret of carbon by impregnation; for although, like the majority of volatile substances, it penetrates deeply, it evaporates quickly. He adds that he has always worked on relatively limited points, and that, for instance, he had never ventured in the treatment of vaginitis to touch the whole of the vaginal mucous membrane.

ECHEVERRIA ON RESECTION IN COMPOUND FRACTURE OF THE ANKLE.—The opinions of surgeons vary greatly as to the treatment of these compound fractures. Dr. Echeverria has (*Thèse de Paris*, 1874) given an account of most of these contradictory opinions, analysed a certain number of facts, and prepared a table of the different varieties of torsion, with the view of offering a solution which may be useful to surgeons. His table comprises cases of complete resection, which are the least numerous; then a large number of partial resections, of the lower end of the two bones of the leg, of the tibia alone, and of the fibula alone, with the corresponding results. The conclusions which he draws are these. 1. Total or partial resection is indicated when the bones of the leg protrude from the wound, or when the patient is powerless in consequence of his fracture being irreducible. 2. It should, however, be avoided when reduction is easy by an apparatus, or when there is wrongly consolidated fracture of a neighbouring bone threatening gangrene of the soft parts, or considerable contusion of them; fractures of the tibia, with fissures extending into the substance of the bone, etc., are indications against the operation. The subperiosteal method should be preferred. Absolute immobility is

one of the conditions of success. Cure takes place by ankylosis or pseudarthrosis. This operation is a less serious one than amputation; it preserves the limb, and exposes the patient to less danger than simple resection. There may not be any shortening on account of the bony reproduction; but, if the contrary should occur, it is easy to remedy it by means of an appropriate covering for the foot.

TERRILLON ON CONTUSION OF THE LIVER.—In the number of the *Archives de Physiologie* for February, Dr. Terrillon relates the results of certain experiments performed on dogs. He omits to mention whether these experiments were performed while the animals were under chloroform. Indeed it does not seem that, if they were in this condition, they would have been spared much pain. The description of the proceedings here given is translated verbatim from the author.

The contusions were made by sharp blows on the right hypochondrium, the dog being placed on his left side. Mallets of different forms were used; in some of them the striking surface was narrow, in others broad and spread out, in order to affect a larger surface. It will be easily comprehended that the exact force used cannot be even approximately stated; but I will use the expressions "contusion forte" and "contusion très violente" to indicate the difference which existed. The wounds were made by means of a knife plunged into the liver perpendicularly to its surface, in order to make a deep section. In other cases, a longitudinal cut was made not deeper than about one centimètre. Lastly, I have in two cases crushed one of the lobes of the organ between my fingers, in order to produce a rupture with irregular edges.

[It appears to us that the results obtained by the operator, however important they may have seemed to him, could never in any way justify such cruel proceedings. The benefits accruing to the human race are the usual excuses made in favour of vivisection; but in this case that plea cannot be used as an excuse. The morbid conditions produced must have been of such a nature as to be of excessive rarity, if, indeed, they ever exist in mankind. This fact renders the results obtained by the operator of such trifling importance that it is useless to notice them. One would like to know what the Society for the Prevention of Cruelty to Animals would have said, had these operations been performed in England.—*Rep.*] W. KESTEVEN, JUN.

HUTCHINSON ON TRAUMATIC NECROSIS OF THE CRANIAL BONES.—The second of Mr. Jonathan Hutchinson's course of lectures on injuries of the head (*Medical Times and Gazette*, February 27 and March 6), is devoted to clinical remarks on traumatic osteitis, necrosis, and pyæmia.

Laceration of the pericranium, and consequent inflammation and death of the portion of bone so exposed, is of far more serious consequence after injuries of the head than any secondary effects likely to ensue in the brain itself. This is owing to the frequency with which necrosis of the cranial bones gives rise to meningitis, or to pyæmia, or both. Pyæmia is the greater danger of the two: it may be induced by the death of a very small area of bone; whilst, if any considerable area be denuded, the recovery of the patient is the exception rather than the rule. This, however, only refers to traumatic necrosis—the prognosis in cases of necrosis from

disease, *e.g.* syphilis, is more favourable. Not only may the local damage appear to be very slight, but the constitutional state of the patient may appear highly favourable to recovery; the patient may be in the most excellent condition and the wound itself look perfectly healthy up to within a day or two of the first rigor. It has been suspected by some that residence in a hospital atmosphere favours the occurrence of this complication. Mr. Hutchinson thinks that proof of this is wholly wanting: several of his most typical cases occurred in those who had been at home until the serious symptoms supervened and were only brought to the hospital because pyæmia had set in.

Mr. Hutchinson thinks that the use of the trephine in the first instance rather diminishes the risk of pyæmia; out of all the cases in which he has performed this operation pyæmia has occurred but once: at all events, his confident opinion is, that the surgeon may quite put aside any question of increased risk of pyæmia and trephine, or not, in any case as the circumstances seem to require.

J. W. LANGMORE, M.D.

DEMARQUAY ON A NEW MANNER OF OPERATING FOR STRANGULATED UMBILICAL HERNIA.—Dr. Demarquay, in an article in the *Tribune Médicale*, quoted in the *Bulletin Général de Thérapeutique* for February, describes an operation in which an oblique incision is to be made on the left side from the middle of the hernial tumour on to the abdominal wall. The integument and superficial fascia having been divided, the neck of the sac is to be reached and a small incision made into the lower part of it. The left forefinger is then to be introduced through the opening, and the edge of the hernial aperture divided to the extent required by the case. This incision is to be made on the left side, and through the thickness of the abdominal wall. The wound is to be afterwards closed very carefully by sutures and covered by collodion. The right side is avoided in the operation on account of the proximity of the umbilical vein, and the middle line presents an objection in the linea alba. By this operation the hernial sac is only injured to a slight extent, and air is not allowed to enter the abdominal cavity.

[It is evident that this operation would be insufficient in those cases of umbilical hernia where the strangulation is due to twisting of the intestine in the sac, or to the presence of old bands of adhesion. This modification cannot be said to be new to English surgeons.—*Rep.*]

Dr. Demarquay expresses a hope that this limited operation, performed early, may lead to good results. He says that what is wanted for success in the hospitals in Paris is early operation in cases of strangulated hernia.

[London surgeons would echo this statement. Delays, and the administration of aperients before the cases reach the hospitals, too frequently prevent the operation from being the means of saving life.—*Rep.*]

SYPHILOGRAPHY.

VAN BUREN ON THE VITALITY OF THE SYPHILITIC POISON.—Dr. Van Buren relates in the *American Archives of Dermatology* for January, two interesting cases of constitutional syphilis which, as he says, illustrate several controverted points relating to that disease.

The first is that of a physician who, while a student, got a small insignificant primary sore, for which he had no treatment. It was followed by a slight papular rash; for this he took some laxative medicine, but no mercury in any shape. The rash disappeared, his health remained perfect, and no further ill effects followed. Nine years after the chancre, a swelling appeared upon the cranium; this caused no uneasiness and was disregarded; in fact, its nature was not suspected, so completely had the long interval of health calmed the patient's apprehensions. The node remained solid, hard, and untreated for eleven years, the general health continuing vigorous. But now the patient was prostrated by a severe illness, having no relation to syphilis, and on recovering from it the node softened. It was opened as an abscess, but, instead of healing, the edges sloughed extensively, exposing the bone over a circular area more than two inches in diameter. And this was the state of the patient, the bone being necrosed, when a year later he came to consult Dr. Van Buren.

Case 2.—A gentleman acquired a slight urethral discharge, for which he was treated with nitrate of silver injection, but took no mercury. A year after this he married and had one child; his wife never conceived again, but she remained well and had no miscarriages. She was treated by a specialist for some uterine displacement, the result of this confinement. The child also grew up healthy.

Twelve years after this urethral chancre (as Dr. Van Buren believes it to have been) some ecchymatous spots appeared on the patient's legs; for these he was treated with arsenic, but Dr. Van Buren states that when he came to him the scars of these 'boils' were clearly characteristic of syphilis. A year later the patient's general health failed; he had hemiplegia, double vision, loss of memory, and other evidences of failing brain-power. He was told that he was threatened with softening of the brain, that he must give up his work entirely and travel. He accordingly came to Europe, and in the course of a year lost most of his nervous symptoms; but a few months after his return home he was attacked with rapidly destructive ulceration of the soft palate, laryngitis, etc. The appearance of the throat when he came to Dr. Van Buren was most characteristic of tertiary syphilis; he was at once ordered iodide of potassium, and this rapidly effected a cure.

1. These cases exemplify the not unfrequent exceptions to the rule, that a mild beginning in syphilis portends a mild course for the whole disease.

2. Certain authors have boldly proclaimed that mercury given early in syphilis is often (some say always) the cause of the appearance of the tertiary lesions, or at least of these being severe. Neither of these patients took any mercury, yet both suffered from severe sequelæ after years of quiescence.

3. Others have stated that iodide of potassium is only efficient after a previous use of mercury. The second case refutes this completely—the remedy acted like a charm.

4. This case also goes some way to confirm the opinion of those who state that a man, no matter in what period of syphilis he may be, may, if he do not poison his wife, have a healthy child.

MATERIA MEDICA AND THERAPEUTICS.

SOLGER AND OTHERS ON THE REMEDIAL VALUE OF NITRITE OF AMYL.—A discussion on this subject took place at a meeting of the Berlin Medico-psychological Society on December 7 (*Berliner Klinische Wochenschrift*, February 15, 1875). It was opened by Dr. Solger, who gave a brief account of the experimental results arrived at by Filehne. The latter attributes the blushing caused by inhalation of two to five minims of the nitrite to paralysis of a centre, situated in the brain, which presides over the innervation of a particular vascular region. The vagus-centre is temporarily paralysed at the same time; hence the quickening of the pulse. Solger observed that, in his own case, prolonged exposure to an atmosphere charged with the vapour of the drug caused first drowsiness, and then wakefulness; the latter being attended by warmth of the extremities. He suggests that other vaso-motor centres, such as those shown by Goltz to exist in the spinal cord, may also be paralysed by the nitrite, its action on the vaso-motor centre in the brain being only the first and most sudden of the series. Brilliant results were obtained from the drug in certain forms of epilepsy and loss of consciousness. Its action in vertigo proved capricious; it failed to relieve this symptom in two cases in which it was connected with malarial poisoning, and yielded to the administration of quinine. The vapour was given to an infant under twelve months old, suffering from one-sided clonic convulsions; the usual physiological effects ensued, but the convulsions were in no way modified. Subsequent inhalation of chloroform checked them for a considerable time. An adult, suffering from epileptic fits ushered in by an aura in the right leg, was directed to inhale nitrite of amyl as soon as the aura made itself felt; this

was invariably found to prevent the subsequent loss of consciousness and convulsion. For convenience of administration, Solger recommends the use of large capillary tubes, containing three to five minims each; these are charged with the nitrite and sealed at both ends; when required for use, one tube is folded in a bit of rag and broken up with the fingers, thus furnishing a sufficient dose of the vapour.

Jastrowitz stated that he had found the drug useful in asthma, but quite useless in patients suffering from melancholia. He doubted whether the hyperæmia of the cerebral vessels occasioned by the nitrite extended to the entire brain; the absence of any visible change in the blood-vessels of the optic disk, either during or after inhalation, leading him to believe that the dilatation of the arteries is confined to particular regions of the brain.

Sander corroborated the statements of Jastrowitz as to the occasional benefit derived from vapour of nitrite of amyl in asthma. He found it useless in the psychoses, and in epileptic fits not preceded by an aura. In two cases, the cessation of inhalation was followed by alarming symptoms of collapse. This may perhaps be explained by an observation of Schüller's, who found that the dilatation of the arteries of the pia mater under the influence of nitrite of amyl was followed by a marked narrowing of their calibre.

E. BUCHANAN BAXTER, M.D.

CHOUPEE ON THE MODE OF ACTION OF THE MOST COMMONLY USED EMETICS.—In the *Archives de Physiologie*, Dr. Choupee relates the results of the administration of emetine, tartrate of antimony, and apomorphine. The animals experimented upon were dogs. The drugs were administered by the mouth, or injected either into the veins or the subcutaneous tissue. The results obtained from these experiments are shortly as follows.

The mode of action of the most commonly employed emetics is not the same in every case.

1. The more the phenomena which precede or accompany vomiting are examined, the greater will be the differences discovered.

Ipecacuanha, and its alkaloid emetina, however they may be introduced into the system, produce vomiting, by direct irritation of the terminal branches of the pneumogastric nerves, in the mucous membrane of the stomach.

Apomorphine and tartrate of antimony have a double action; on the mucous membrane of the stomach, and on the medulla oblongata.

2. The difference between them consists in the fact that, with the antimony, the effect is procured more rapidly by introducing it into the stomach than by subcutaneous injection. With apomorphia, the latter mode of procedure gives the best result. These facts prove that antimony has a more direct action on the terminal ends of the nerves, and that apomorphia more directly affects their central origin.

W. KESTIVEN, JUN.

OBSTETRICS AND GYNÆCOLOGY.

NETTER ON THE POSSIBILITY OF CURING ACUTE PERITONITIS BY INJECTING A SUFFICIENT QUANTITY OF TEPID WATER INTO THE PERITONEAL CAVITY.—Dr. Netter (*Revue Médicale de l'Est*, January 15, 1875) quotes some remarks made

by Kœberlé in 1867, on a case of his in which acute peritonitis threatening death occurred after ovariotomy, but was checked, and the patient saved by incision into the right flank, where he detected dullness, and the escape of a quantity of red serum from the peritoneal cavity. He gives extracts from the speeches of Kœberlé, himself, and others, at a long debate which followed the reading of this case at the Strasbourg Medical Society. The cause of the speedy relief when the fluid is detected and let out at once in these cases was the chief ground of debate.

Kœberlé, while insisting on speedy action, attributed the danger to the fluid becoming rapidly septic from its contiguity to the intestines.

Netter objected to this—1. Because of the rareness of true idiopathic peritonitis (*i.e.*, excluding cases of perforation, etc.); 2. Because of the rareness of this typhoid or septic form itself. He considered the first product of the inflammatory action as the most actively dangerous, and compared it to the acrid mucus which is discharged from the nostrils at the onset of coryza. He also pointed to the numerous successful ovariotomies of Kœberlé and others, successful in spite of handling of the parts, introduction of instruments, exposure to the air, etc., of the peritoneal cavity and its contents. These successes he attributed to the thorough cleansing of the peritoneum at the time of operation, and the speedy evacuation of any fluid which gathered afterwards.

The possibility of applying this principle to other forms of peritonitis was suggested by some of the speakers, and reflection on the subject led to the present proposal by M. Netter.

He considers it would not only be justifiable, but right, in cases of acute peritonitis, to make a small opening into the peritoneal cavity, and inject sufficient tepid water to thoroughly dilute its contents and form an artificial ascites. If relief follow, the injection should be repeated. He supports his proposal by the facts observed in the similar diseases of the pleuræ. When the pleura is dry the fever runs high, but when effusion comes the symptoms abate; and when effusion occurs at the onset often there are hardly any symptoms. Even when some fluid is effused into the peritoneum it gravitates, and the intestinal and upper surfaces become glued with the lymph. He affirms—1. That the liquid secreted in acute peritonitis has only noxious properties in proportion to its concentration; 2. That, largely diluted with water, it loses these noxious properties.

He gives in full an old paper by Dr. Herlin in 1767, on some experiments which he and others made on cats and dogs, ligaturing the bile-duct and puncturing the gall-bladder, and letting the bile into the peritoneum, afterwards practising warm-water injections. The animals appeared none the worse for the operation, though dogs, as Netter points out, are specially liable to peritonitis. He arrives at the following conclusions.

1. It is possible to cut short acute peritonitis by injections at its commencement.

2. If Herlin's experiments be repeated without the injections and the animals die, it will be because the injections were not used.

3. Since it has become a recognised practice to use injections when peritonitis comes on after ovariotomy, etc., so it should be in the other forms of peritonitis where there is no surgical opening to begin with. He considers the adhesions formed by the intestines in puerperal and other cases a cause of the extreme gaseous distension, and consequent

dyspnœa and collapse; if the injections alone will not separate these adhesions, aid may be given by simple punctures, to let out the gas. He quotes from Kœberlé that these adhesions lead to little pouches full of serum or pus. In a note at the end of the paper he advocates leaving the wound open after herniotomy, and injecting if necessary.

[The reporter has several times noticed the pouches referred to in *post mortem* examinations, and that they are surrounded by extra inflammatory action; mere puncture and draining of course gives no exit for such collections of serum or pus.—*Rep.*]

J. KNOWSLEY THORNTON.

DERMATOLOGY.

FAYRER AND DA SILVA LIMA ON GOA POWDER AS A CURE FOR RINGWORM.—The *Medical Times and Gazette*, for October 24, contained a communication from Dr. Fayrer, calling attention to a remedy which has a high reputation throughout India for the cure of certain skin-diseases which are common in that country, and especially of a somewhat obstinate affection called 'Indian Ringworm.' This remedy, which Dr. Fayrer himself has 'found to be most certainly and rapidly effective,' goes by the names of Goa Powder, Chrysatobine, or Poh di Bahia. Dr. Fayrer commends the powder, which he thinks has not yet become very generally known in the profession, to the notice of dermatologists, and suggests a more extended use of it in this country. He adds, 'I regret that I am unable to state what Goa powder consists of, but I believe it to be a production of the vegetable kingdom.' He applied for information on this point to Mr. Hanbury, but without success; 'the composition as well as the place of manufacture of Goa powder seem alike secrets.' It is a fine yellowish powder, without smell or taste; the mode of application is to dissolve a few grains in vinegar or lime-juice to about the consistence of cream, and to paint this over the eruption and for a little distance beyond its margin on to the sound skin; this may be repeated after a day or two. Two or three applications rarely fail to effect a cure.

In a subsequent number of the same journal, p. 547, Mr. Gaskoin, of the British Hospital for Diseases of the Skin, says that he has experimented with this powder, and has not been altogether satisfied with the result. He states, that it causes considerable irritation of the skin; he has, however, been in the habit of rubbing in the powder instead of merely painting it over the surface.

In the *Medical Times and Gazette* of March 6, Dr. J. L. Paterson, of Edinburgh, publishes an interesting letter from Dr. Da Silva Lima of Bahia, in which the mystery as to the composition of Goa powder seems to be satisfactorily explained. He says that the powdered medulla of a tree, called in Brazil araroba, is there a popular remedy for herpes circinatus and other similar affections. The tree which furnishes this powder grows only in the interior of the empire, and has not yet been botanically identified; it belongs, however, to the natural order Leguminosæ. The powder is known throughout South America as po' di Bahia (Bahia powder), and is also exported in considerable quantities to Lisbon, whence it is probably reshipped to the Portuguese settlement Goa, and thence distributed over India under a new name. The physical properties and therapeutic effects of araroba powder and of

Goa powder seem to be identical, except that the latter is less energetic, owing no doubt to adulteration. Dr. Da Silva Lima recommends the following formula: Araroba powder gr. xx, acetic acid ℥x, benzoated lard an ounce. He has found it very efficacious in the parasitic skin-diseases mentioned by Dr. Fayrer and also in mentagra.

O'NEILL ON THE PRESENCE OF A FILARIA IN 'CRAW-CRAW.'—Dr. John O'Neill, Surgeon R.N. (*Lancet*, February 20), describes 'craw-craw' as a contagious skin-disease, endemic among the negroes on the west coast of Africa, which in most of its symptoms closely resembles scabies. He appears to have demonstrated the fact that the irritation is due to the burrowing in the true skin of a minute filaria, one-hundredth of an inch in length, of which he gives drawings. He says that the disease resists the native remedies, and he does not state that his European brethren have been as yet more successful. Sulphur, at all events, 'is of doubtful efficacy.'

REVIEWS.

Diseases of the Kidney and Urinary Derangements.
By W. HOWSHIP DICKINSON, M.D., F.R.C.P.,
Physician to and Lecturer on Pathology at St. George's Hospital. In Three Parts. Part I. Diabetes. London: Longmans, 1875.

This work forms a careful and complete treatise on diabetes, based upon the view that it is due to a derangement of the nervous system. The volume commences with a concise account of glycogenesis and glycosuria, in which the author adheres to the opinions of Bernard, whose latest views were fully expounded in the lectures published in the first volume of the LONDON MEDICAL RECORD. The only point in which Dr. Dickinson is disinclined to accept Bernard's views is that as to the theory of glycosuria; for, although he follows that physiologist in the idea that increased circulation through the liver, due to vaso-motor derangement, is the fundamental factor in the affection, yet he holds that there is rather a substitution of sugar for glycogen than that the glycogen is really increased in amount. In the chapter devoted to the pathology of diabetes, Dr. Dickinson

dwells at length upon the changes which he discovered in the nervous centres, changes which may be briefly summed up as consisting in dilatations of and hæmorrhage from small arteries, chiefly in the white matter of both the brain and the spinal cord, leading to distension of the perivascular canals and consequent excavations in the nervous tissue, excavations frequently large enough to be viewed by the naked eye, and containing generally shreds of imperfectly formed connective tissue mingled with hæmatin crystals and the remains of blood-vessels. This part of the work is profusely illustrated with well-executed engravings, together with the two plates which accompanied the author's paper on the subject published in the *Medico-Chirurgical Transactions*. He also adds one case in which, in addition to these excavating changes, there was widespread 'miliary sclerosis' of the white matter of the brain and both white and grey matter of the spinal cord. The perivascular changes point, he thinks, strongly in favour of the view (which is in harmony with Bernard's results in artificial glycosuria) that diabetes is due to nervous irritation rather than interruption or loss of nervous power; the nerve-tissue being perfectly natural up to the margins of the excavations. In the liver, more or less hyperæmia was the prevailing condition among twenty-seven cases examined, in two cases associated with widespread thrombosis of the portal veins, and in one with remarkable areas of capillary dilatation. With regard to the disease of the lungs, frequently present in diabetes, he regards it, like Drs. Wilks and Pavy, as not being tubercular, but rather as a chronic excavating pneumonia. In the kidney he has met mostly with various degrees of congestion, often associated with overgrowth and fatty degeneration of the renal epithelium. The section on pathology terminates with analyses of the blood by Simon, and a few remarks on the prevalence of glycosuria among the insane. The subjects, distribution and causes of diabetes, form the third chapter, hereditary influence and mental emotion being stated to hold the first place in its etiology; while numerous instances are given of traumatic and obvious morbid lesions in the brain as producing the disease. The sketch of the clinical course of the disease is very graphically rendered, special mention being made of the temperature of the body, and of diabetic cataract, the non-advisability of operation in the latter affection being strongly urged. A chapter is devoted to the full consideration of the characters of the urine; and the concomitant variation in the amounts of urea and sugar excreted is well shown. Under treatment, restricted diet, opium, iron, strychnia, cod-liver oil, and, if necessary, aperients, are alone thought to be of value; and the author expresses himself as a strong opponent of the skimmed milk treatment. The subject of diabetes mellitus is concluded by the details of four cases, in which full analysis of the urine was made, showing the effect upon the urine and the natural course of the disease of various methods of treatment employed. The subject of diabetes insipidus is then treated, and its origin in disorder of the nervous system upheld; this disease is also illustrated by the notes of four cases, three occurring in childhood and one in a man sixty years of age, in which it apparently resulted from the compression of the abdominal sympathetic by post-peritoneal cancer. A comparison of the two forms of diabetes, as regards the influence of diet upon the disease, terminates the volume, from which it would

appear that in diabetes insipidus a vegetable diet caused no increase in the quantity of urine, but a decrease in the discharge of urea; in diabetes mellitus it produced increase in the quantity of sugar and urine, and a temporary excess in urea; while under a meat diet the subjects of the former disease did not improve like those suffering from the mellitic form.

The work, of which the above is a mere summary, is one of great value and interest. It forms a clear and full exposition of the disease of which it treats, and is written in a style at once scholarly and engaging. Although it would, perhaps, be premature to affirm that the nervous origin of diabetes mellitus is here finally settled, yet this work will rank as the first in which the pathology of the disease has been shown to be in accordance with physiological doctrine; and, if confirmed by subsequent observers, the researches of Dr. Dickinson on the changes in the nervous system in diabetes will always be regarded as marking a great advance in pathology.

The second part of the work on 'Diseases of the Kidney and Urinary Derangements,' of which this volume forms the first, is to comprise a second edition of the author's well-known treatise on albuminuria; while the third part will deal with the organic renal changes which do not come under the heading of albuminuria; abscess, embolism and thrombosis, growths and cysts, renal calculi, suppression of urine, hæmaturia, and chyluria.

S. COUPLAND, M.D.

NEW INVENTIONS.

SALICYLIC ACID WOUND-DRESSING COTTON WOOL.

Messrs. Krohne and Sesemann have not been slow to bring into practical use the antiseptic properties of salicylic acid, to which much reference has lately been made. Our readers are already acquainted with the favourable reports which have been made of the antiseptic and unirritating properties of salicylic acid. Messrs. Krohne and Sesemann say that salicylic acid wound-dressing cotton is used in the same manner as Brun's wound-dressing cotton. To prevent it adhering to the wound, a piece of muslin previously dipped in a solution of salicylic acid (one part acid to 300 parts hot or 1,000 cold water), is first placed over the wound, on which the cotton is placed and then fastened with a bandage. This dressing may remain untouched for days or even weeks; in the latter case it is only necessary to saturate it now and then with a watery solution (1.300) of salicylic acid. For this reason it is cheaper and preferable to any other dressing. Balls of this cotton wool covered with muslin are used instead of sponges.

We hear that it has already been tried and favourably reported upon by many hospital surgeons and obstetricians.

CIGARS DE JOY.

These 'cigars' have long been in use abroad, and are well known in this country. They form very convenient and useful means of treating a disease which is often highly intractable. Asthma, hay fever, and all spasmodic affections of the respiratory organs which baffle many well-considered means of treatment, will generally yield entirely and are always relieved by the inhalation of medicated fumes. The 'Cigars de Joy' are rolls of prepared

paper impregnated with stramonium and other medicinal herbs.

The method of using is simple enough. They need only to be lighted and to be smoked as the Greeks are in the habit of smoking cigarettes of light Turkish tobacco, namely, by taking a deep sighing inspiration as each puff of smoke is drawn into the mouth. This sucks the medicated fumes into the air-tubes, and impregnates the air which passes into the lungs with the volatilised chemicals with which the cigarette-paper is impregnated. The local application of the medication has a very rapid effect in soothing bronchial irritation and relieving the spasm of air-tubes. One cigar at a time usually suffices. Many varieties of papers and cigars have been introduced since first the 'cigars de Joy' were brought into notice; but none of the more recent introductions have proved more generally useful than these; and thus, although they may have been partly lost sight of in the little crowd of new aspirants for favour, they are not less deserving of notice than ever, for they have lost none of their therapeutic merits.

REMIN'S ESSENCE OF THE BEST.

Under this name has been introduced a pleasant alcoholic stimulant, to which some nutritive elements have been added. We have Dr. Hassall's authority for saying that it is well-adapted for its purpose, and made of sound and wholesome materials. The sphere of usefulness of such compounds must be within the physician's discretion. On the one hand it is sometimes useful to be able to prescribe a stimulant which comes to the patient as something else in form than ordinary 'wine and beef-tea'; on the other hand, it is not desirable that under harmless names alcoholic stimulants should obtain currency as popular drinks. This compound, therefore, may be useful as part of the physician's list of remedies, but it would not be desirable that it should be regarded as anything else than a variety of flavoured alcohol, which is to be administered and employed under the proper safeguards against abuse as a means of tipping.

ARNOLD'S NEW CLINICAL THERMOMETER.

This little pocket clinical thermometer has many advantages. It is portable, firmly mounted, with a well-devised 'bayonet catch,' and graduated with a very legible and indelible reading-scale. They are well tested and accurate instruments, and combine almost all the requirements which can be looked for in an instrument of the kind.

MISCELLANY.

DOCTOR'S CARRIAGES. — A venerable physician of Philadelphia, still living, Dr. Condie, the author of a book on *Diseases of Children*, would never keep a carriage, notwithstanding his large practice, and is made responsible for this *mot*, 'If a doctor drive one horse, it indicates physical weakness; if he drive two, mental weakness.'

MEMORIAL TO SIR RANALD MARTIN. — A meeting to consider the subject of a memorial to Sir Ranald Martin will be held at Willis's Rooms on Thursday, the 25th inst., at 4 P.M., when Sir Galbraith Logan has consented to preside. It is contemplated that the proposed memorial shall be in the form of some kind of prize or medal in connection with the Army Medical School at Netley.

INSANITY IN AMERICA.—The Report of the Commissioners of Lunacy to the Commonwealth of Massachusetts estimates the number of the insane in that state at over four thousand, of which two thousand two hundred and fifty-six are in hospitals, four hundred and thirty-eight in almshouses, and the rest in private families. According to the National and State censuses in America, there is an increase of insanity in a ratio beyond the increase of population, and it is most marked in the foreign element.

STUDIES ON WOMEN.—Dr. Edward Reich, of Jena, has published a work under this title, containing a mass of information on the sex, especially on their vital statistics. It shows that the female sex is not only less liable to violent deaths and accidents but also to severe disease. In a million of inhabitants in Prussia, 58,817 men died of old age and its attendant weakness, while 95,116 women survived to be thus registered. So far as the liability to 'sudden death' is concerned, the figures stand 68.51 men to 52.60 women. The author makes the suggestive deduction from his studies, that wherever statistics show a mortality among females much exceeding that among males, we may have 'the greatest certainty that that locality demands the most earnest attention of the philanthropist. Vice and crime are rife there, and when a pestilence breaks out there, its devastations will be terrible.'

THE POPULATION OF CHINA.—The Abbé David, who has spent many years in exploring the Chinese territories, and in studying the manners and customs of the inhabitants, states that the number of 100,000,000 of inhabitants given by the majority of statisticians as the sum total of the population of the Chinese empire is entirely inaccurate. He attributes the error to the terrible ravages in certain political subdivisions which had many times been in a state of revolt, and in which organised massacres had reduced the population to one-half, nay, sometimes, to one-fifth, the original population. In the province of Kiangsi, which is the most sparsely populated, the population is 4,000 inhabitants per canton, and there are not fewer than 4,345 cantons; which makes up a total of 17,380,000 inhabitants. The majority of the eighteen provinces composing the middle Empire are undoubtedly more thickly populated than the province of Kiangsi; taking, however, 17,380,000 as the average, the total amount of the population would not be less than 300 millions.

THE OXFORD AND CAMBRIDGE BOAT-RACE.—Much has been written on the alleged injury to health from the over-exertion induced by the Oxford and Cambridge boat-race. Dr. H. L. Bartlett, in a paper on 'Physical Culture,' published in the *New York Sanitarian*, thus summarises all the data which have been collected on the subject. Some years since public attention was called to the subject of athletic sports in connection with college and university life, and the statement was made by popular journals that the exercise requisite to make a student proficient as a champion in rowing or ball-playing, was dangerous to life, and detrimental to health. To settle this question, Dr. J. E. Morgan took the trouble to learn the personal history of all the crews engaged in the Oxford and Cambridge boat-races from 1829 to 1869, a period of forty years, and comprising thirty-two crews, including 294 oarsmen. Of these, thirty-nine had died, in the mean time, of the following diseases: of fever, eleven; consumption, nine; accidental causes, six; heart affections, three; diseases of the brain, two; inflammatory attacks, two; general paralysis, one; calculus, one; erysipelas, one; Bright's disease of the kidneys, one; cancer, one; lupus, one. On this Dr. Bartlett remarks that surely these are not causes of death induced by over-exertion. According to the report of the Registrar-General of Great Britain, the mortality in civil life from diseases of the heart and lungs is forty-six per cent., and among soldiers and sailors, still larger, while among the Oxford and Cambridge oarsmen the mortality was only thirty per cent. from the same causes. According to Dr. Farr's life tables, the average duration of life after the age of twenty is forty years.

In other words, the person who has reached the age of twenty will probably live till the age of sixty. Dr. Morgan found the average of the Oxford crew of 1829 to be forty-six years, and the Cambridge crew of the same year to be 48.6, or an excess of from six to eight years beyond the average of human life, and concludes that the University oarsmen, though their labour be excessive at times, are more robust, better scholars, and live longer than the other students. The Rev. H. A. Morgan, brother of Dr. Morgan, says, 'I have myself rowed in over a hundred eight-oared races, on the Cam, and have mingled much with rowing men, but have never seen injurious effects from the rowing.' The popular idea, therefore, that it is injurious to the students of our colleges and universities to join in athletic sports, even of a severe character, is not borne out by facts. On the contrary, experience proves that they who are the most successful ball-players and oarsmen are, as a rule, the best students. It is reasonable to suppose that this should be so, since study is a great tax upon the physical strength and endurance of a man, and he who has the most stamina, other things being equal, will win. In connection with this subject the Rev. Dr. Haughton in his *Animal Mechanics*, writes: 'A good idea may be formed of the rate in which the muscles give out work in a boat-race, by comparing this work with the average daily work of a labourer. In many kinds of labour there are four hundred foot-tons of work accomplished in ten hours. The oarsman performs in one minute the one hundredth part of his day's labour, and if he could continue to work at the same rate, he would finish his day's task in one hour and forty minutes, instead of the customary ten hours. The work done, therefore, in rowing one knot in seven minutes is, while it lasts, performed at a rate equal to six times that of the hard-worked labourer.' It would, therefore, appear that although no specially injurious effects have been traced to the strain of the boat-race, this immunity must rather be attributed to the short time during which the exertion is kept up than to any other reason.

THE MOST ECONOMICAL MODE OF LIGHTING PREMISES, where natural daylight is obstructed, owing to the small size of windows or the proximity of buildings, is by adapting one of those useful Daylight Reflectors. Mr. Chappuis, the patentee, of 69 Fleet Street, manufactures them of various qualities, in order to suit the purse of rich and poor. They are in general use all over London, and in almost every town of the United Kingdom; with the aid of this invention, gas being done away with in day-time, the twofold purpose of health and economy can be served thereby.—[Adv't.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MARCH 24, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

MEYER ON DEFORMITIES DUE TO ARRESTED DEVELOPMENT IN IDIOTS.

The following is an abstract of an article by Professor Meyer, of Göttingen, in the *Archiv für Psychiatrie*, vol. v. no. 1. Of the bodily peculiarities seen among idiots, only those, according to our present scientific basis, must be regarded as typical which, in the microcephalic, are known as deformities of the head. Of their dependence on the fundamental lesion, the cramped development of the brain, no one has ever doubted. One has only to compare any of the often called idiot-skulls with that of a chimpanzee or other anthropoid ape, to see at once that the prognathousness of both depends on quite different conditions. In the ape there is a truly colossal development of the teeth and a resulting overgrowth of the upper jaw, especially in its alveolar portion; while the face-skeleton of the microcephalic is not only not excessively developed, but, judging from a limited number of observations, absolutely below the normal size to a very considerable degree. The growth of the face-bones is really dependent on the development of the base of the skull. Should this, as in all the true microcephalic, remain below the normal, it at once sets up an impediment to the normal development of the face. This face, which was before in itself too small, now projects, because the skull part has proportionately retrograded, and in the frontal region has much receded. The prognathousness of apes (also of negroes) is, then, an absolute and positive one, whilst that of the microcephalic is only relative and negative.

As to the general corporeal formation of low idiots, æsthetic modes of viewing them seem to have prevailed. Authors have busied themselves about the strange, repulsive, horrible aspect. Still it must be apparent that a diminution of the brain which so impairs the development of the intellect, influences also the growth of the body in a definite degree. Impairment of innervation as a rule entails that of nutrition, and it is well known how pathological precedents in the central apparatus influence the ultimate growth of limbs, at times, indeed, that of half the body. Rösch has already called attention to the stagnant and ill-developed aspect of the whole body in cretinous and idiotic children, as one of the most striking and constant appearances. It does not appear that, beyond the general weakness of development and impairment of nutrition, any reference has hitherto been made to the disproportion of the extremities to the body.

The investigations which follow comprise the first efforts to fill up this gap, and to show the influence of arrested brain-development on that of the body.

A harmless idiot, C. Fuge, aged twenty-eight, was admitted to the Göttingen Asylum. A supporter of

the 'Descent-theory' might in him have recognised retrogressive anthropoid traces, just as the well-known idiot Sophie Wiss showed her atavistic disposition by climbing and riding on dogs. Thus for years he had a strong affection for horses and donkeys, which he would embrace and mix with on every occasion. If a waggon passed by the street door, he would rush out of the house and stand by the horse. His pet place of resort was at a neighbouring cabman's, where he always occupied himself in the stables. This propensity for running after horses was the occasion of his being brought before the police, and transferred to the asylum. Apart from a few syllables, which, as in young children, were more breathed out than spoken, his language in no degree resembled human speech. It is doubtful whether in this case the want of speech denoted intellectual impotence, and should be regarded as typical of the lowest state of intellectual development, proceeding either from want of ideas or from want of the necessary movements of speech-mechanism. The former would have nothing to say, the latter no necessity to speak. The difficulty in this case of performing the more minute movements of articulation much resembled the defective bodily formation. Even eating was badly performed, for the food was put into the cavity of the mouth, far behind the teeth, and, after the most limited chewing, swallowed, the teeth showing all the time. He soon learnt to understand the wishes of the attendants and the rules of the asylum, and would give information of any small irregularities. At first unclean, he soon learnt better. He could express astonishment, surprise, and other emotional conditions by lifting his arms, opening his mouth, etc. He was never seen to laugh or weep, but when depressed or frightened he squatted on the floor, hanging his head down with drooping eyelids. Only when very much annoyed, as when his food was taken away, did he utter a few cries. His intellectual endowments were no more than those of a child two years old.

Truly striking was the impression of the figure in the upright position, when approaching anyone, reminding one exactly of Raff's picture of the ape of the Zoological Gardens. Leaning forwards, he rested on the outer border of the feet, the knees decidedly bent, and with a rolling gait. The head was deeply drawn down between the shoulders, and raised up when looking forwards. Grasping, holding, and other movements of the hand were always accompanied with protrusion of the upper arm. The whole of the hand was used—for instance, the handle of a spoon was placed in the palm, and food thrust into the mouth with the clenched fist. Resembling the ape again was the extraordinary mobility of the features under excitement. Forehead and cheeks were at once covered with numerous wrinkles, making the face look that of a much older man, although the general expression before was younger and more childlike. The first traces of a beard showed themselves in his twenty-fourth year, confined to a few bristles on the chin and lower jaw; nothing on the upper lip. On the generative organs were only a few thin fine hairs. The testicles were small; and he had no appearance of sexual desires, nor any inclination towards the opposite sex. When undressed the body was seen to be deformed, as were the extremities. The body was curved backwards, from above downwards, and sidewise. The front surface curved backwards in the same sense. The spinal column, wanting the normal S-curve,

formed a simple bow, and only on attempting to raise the back part of the skull and look upwards was it entirely straightened. The shoulder-blades hung down far from the spinal column, as much on the side as on the back parts of the body. As a consequence, the shoulder-joint stood diagonally forwards, and the arms forwards instead of being sideways. The clavicles were short, and bent backwards slightly at the ends. The muscular system of the extremities was feebly developed, though the general nutrition was good. The feet were short and cloddy; the toes very short, especially the large ones, which scarcely jutted beyond the others. The end of the foot was directed inwards and slightly upwards. The prominence of the calves was more on the outer than the inner side. The posterior external muscles of the right leg on the under side were always contracted, making the foot appear clubbed and the leg too short. The fore-arm was too long, notwithstanding the smallness of the hand. This latter peculiarity was very striking from its deviation from the usual form of the hand. It was very small; much longer in the carpo-metacarpal part and shorter in the fingers than another hand of like size. The thumb, when the hand was completely outstretched, scarcely reached with its extremity the carpo-metacarpal phalanx, and the terminal digital phalanges looked diminutive, scarcely affording room for the nails, and badly adapted for firm seizure. The palm of the hand was flat, limp, and the skin corrugated. The ball of the thumb and little finger ill developed. Then follow two tables of measurements of the hand, compared with those of an equal-sized hand of normal dimensions. At the first look of Fuge's head, the face appears too small and too long, but the skull neither in size nor in form seems abnormal. Closer investigation, however, yielded many considerable deviations both in the face and skull, the latter overtopping in the frontal and still more in the parietal curve, both in front and at the side, the base of the skull and the face. The lateral vaulting seemed like an abscess, and a line drawn in the frontal direction through both parietal bones resembled a somewhat flattened Moorish bow. The face was equally directed with the vertically upright yet somewhat forwardly inclined forehead, giving in consequence an opisthognathous look, Camper's angle being very large. The upper maxilla, palate, and lower jaw were very small. The teeth, which should have stood perpendicular to the alveolar margin, were turned forwards, so that, besides the opisthognathousness, there was alveolar prognathousness. The distance between the angles of the lower jaws was ninety millimetres (three and a-half inches), whilst for a healthy adult they should be, according to Welker, four inches. Though the frontal bone and both parietals were strongly developed, both in length and in breadth, the occipital seemed almost conical, and in form, position and size, like that of a new-born child. The small fontanelle looked like a deep pit, which, in an oblique direction by a crest on the right side of the squama, was connected with the upper line of the neck. The large fontanelle had also a circular depression, which blended with the depressed and wide coronal and sagittal sutures.

The above-given limits of the skull only admit of the conclusion that in the earlier years, perhaps even in the fetal period, an abnormal and retrograde increase in the contents of the skull occurred, in consequence perhaps of a congenital hydro-

cephalus. That the size of the skull was not large is explained by the later absorption of the fluid, and by the influence of this on the development of the brain. But, however satisfactorily this congenital hydrocephalus explains the condition of the anterior and middle portion of the cranium, that of the posterior portion is a riddle. The vertical part of the squamous bone was scarcely two fingers high, and the basal portion not much larger; this leads to the conclusion that, the transverse crista being there, the flat surface did not afford enough space for the insertion of the cervical muscles. It appeared afterwards that the upper part of the squama was the seat of an encephalocele or hydrancephalocele, for soon after birth there was noticed there a round, depending tumour, like an abscess, which gradually and completely disappeared. The position and small size of the occipital bone confirm, what might have been concluded from the position of the head and the downward direction of the eyes, that the foramen magnum was placed too far backwards and less horizontally than in normal skulls. Both these elements, as comparative anatomy shows, are connected, and Daubenton has already written that, 'the farther the foramen magnum is from the occipital protuberance, the more horizontal is it; and the nearer it is, so does it become more perpendicular.' And later on both he and Cuvier thought that the upright position of men and the horizontal direction of the eyes were dependent on the position of the foramen magnum. The plane of the foramen magnum is almost at right angles to the perpendicular of the body, and when prolonged cuts the face at the level of the orbits. Cuvier also shows that the prolongations of the joints of the skull bisect a line drawn from the occipital protuberance to the incisor teeth, and so in vertical positions of the body equipose the head.

Through physiological changes, the occiput became arrested in development, and the foramen magnum and condyloid processes were retained in the position they had at birth. Consequently, at the first attempts at standing upright the body was directed forwards and the eyes downwards, a circumstance which made Fuge draw his head into the neck. The other abnormalities rest on the same pathological basis. The waddling gait of the negro and other races, where the support rests chiefly on the outer border of the foot and great toe, is a necessary result of the posterior position of the foramen magnum; just as in the fetus the spinal column is quite straight, and in the newly born is very little curved, so in negroes and other races, where the foramen magnum is more inclined and less central, the spinal column is straighter than in Europeans. The form of the spinal column and the corresponding prone position of the body, influence both extremities; at first, of course, only in position. One is tempted to refer the shortening and deficient curve of the clavicle to the position of the scapula and upper arm, *e.g.*, in prone positions of the body a considerable impression must be made on those parts which are perpendicular to the long axis, and have the tendency to press from without inwards. As gynaecologists know, the clavicle in the later periods of pregnancy has fully attained its characteristic form, and one is forced to suppose that the above-mentioned influences have been strong enough to transform the human form in the post-fœtal period to that of an ape. The relative length is greatest in men, where the double curve is most pronounced.

Considerably weakened in the short and coarse clavicle of anthropoids, the curve resolves itself in monkeys into a slight bend backwards.

Then follow some observations on the relative lengths of the upper and fore-arm, of the thigh and leg to each other. Observations and measurements on well-proportioned embryos and skeletons show that at first the lower exceed the upper extremities in length, but that later on the reverse occurs, and that in the later periods of pregnancy the difference is comparatively small. To Humphry belongs the credit of having settled the growth of the extremities by measurements at various ages. At the first stage of their development, the upper arm and thigh are proportionately shorter than the fore-arm and leg; gradually the proportion changes, and not till the period of puberty does this change of relation cease. In the *Révue Anthropologique*, 1872, Haüy has shown that the proportion of the fore-arm to the upper-arm in the negro is the same as in the fœtus of white races at five to seven months. Langer has shown that the shape of the hand at birth is completed; from that time it develops evenly; whilst, starting at the sixth week, the fingers are developed by shallow but gradually deepening notches, and the carpus and metacarpus exceed the growth in the earlier months. The proportion changes, however, quickly; in well-developed specimens of the fourth and fifth month the middle and index fingers had already reached the length of the carpus and metacarpus. Fuge's hand shows the embryonic preponderance of carpus and metacarpus, but here the comparison ends, for to his short and weak thumb there is no similitude in the fœtus. In the human hand, more characteristic than the shortness of the hand itself and the length of the fingers is the length of the thumb, whilst, though the gorilla has a larger hand absolutely, it has not only relatively but absolutely a smaller thumb than man. In its whole and separate parts it is not only smaller but also weaker and thinner; and whilst in men the thumb is placed in apposition with the index-finger and reaches almost to the end of the first phalanx, in the gorilla it only reaches the head of the metacarpal bone. As already hinted, the defective, or, rather, most elementary speech depended more on incompleteness of the special speech-mechanism than on want of psychic power. Just so the strong emotional expressions had no outlet of expression. The psychic predispositions to laugh and weep are in idiots more highly developed than those to speak; but the occasions for laughing and weeping must be more rare in them than in most men; it remains then that this failure of emotional expression rests solely on the want of machinery. On the other hand, it would appear that the laughing and weeping mechanism is wanting in the new-born. If, however, in the course of the first three or four months of life it attains perfection, or even works with great power, there is enough to show that the theory of an 'acquired' movement must be excluded. The incapability of expressing one's feelings by laughing and weeping depends on very different causes. The failure may be in the necessary combination of sensory and motor nerve-paths, or in the connection between these with the place of origin of psychic excitation in the central organs. In Fuge's case, as in that of the newly born and monkeys, it may be in the necessary co-ordination of the sensory and motor ultimate apparatus required for laughing and weeping. Should the latter view be admitted, there would be a close analogy between the deformities of

body and extremities and the impediments to the execution of psychic excitations. Bischoff's investigations on the face-muscles of apes, which, just as idiots and new-born children, are incapable of physiognomic expressions, confirm this view. In the young chimpanzee and orang, as well as in hylobates, the face-muscles, including the orbicularis palpebrarum, orbicularis oris, and buccinator appear only as pure skin-muscles, to which from their position, one could give the same names as in men, but which are so little separated from each other that such scarcely seems justified. This is also the case with other apes, and I think that one may well stand by the old assertion that man may be separated from all beasts, and even from the highest apes by the strong development and isolation of his facial muscles.'

[The ape-like varieties of men are not unfrequent in asylums, but hitherto they have not received the scientific investigation which they undoubtedly deserve. It is in the hope of directing attention to the more exact study of these persons, in the way indicated by Dr. L. Meyer in the journal above quoted, that the present article is written.—*Rep.*]

T. C. SHAW, M.D.

THE ELECTRICAL ACTION OF SOOL-BATHS.

BY DR. SCHELLE, OF ROSENHEIM.*

The advice of the physician is constantly asked for as to the expediency of trying a bath-cure. If he have not special experience of it, he ought to be in possession of the best sources of information on the subject, at least if he is to give useful counsel. These sources are, the works on balneology and his own judgment. The knowledge of the literature of balneology is doubtless indispensable to him; but the directions which it gives, are by no means so absolute, or definite, that he may not make a mistake in following them. He must think out the subject, and form for himself the principles that ought to guide him.

I shall now treat exclusively of bathing, not of drinking cures. Our chief aids in studying the effects of baths are, undoubtedly, chemistry and organic physics. The first is nearly exhausted. There is scarcely a bath of any importance whose waters have not been carefully analysed. Organic physics is a comparatively new science, and has been only partially applied, and its application is far more difficult and complicated than that of chemistry. Admirable results are produced by bathing, but the *rationale* of this remains very much in the dark. It is mainly by studying the various forces which operate on the human constitution, that we can hope to advance our knowledge. The point in balneology which I find shrouded in the greatest obscurity, is the influence of animal electricity. It is scarcely alluded to in our handbooks; yet this invisible agent always encircles us, and manifests itself whenever we move from one medium into another, for instance, from the air into water. In fact, the distribution of electricity in the electrical organs is materially affected by the mere immersion of the body in water. This is most evident in water containing mineral ingredients; and in the strong salt-baths so much used in Germany, a great portion of their curative effects is to be attributed to electro-dynamics. Without its agency, most of the

* *Aerztliches Intelligenz-Blatt*, no. 4, 1875.

effects of salt-baths would be quite inexplicable. As my views of the operation of these baths are different from the usual ones, and are founded on ten years' experience of them, I may, perhaps, be allowed to explain them. The therapeutic effects of these baths depend (1) on the heat which they convey to the body; (2) on the electrical changes they produce. In the first respect, their action is antiphlogistic; in the second, it is stimulant.

1. The skin is soaked and distended by a warm bath, while the parts lying immediately under it are comparatively little affected. This may be plainly observed in the tactile papillæ of the fingers. The skin over them swells, while the more solid papillæ remain behind. Along with the swelling of the skin, injection of the capillaries takes place, as shown by its lively colour. This injection is produced by all warm water, whether it be simple or mineral. The injection of the capillaries is so strong that occasionally it leads to the production of a rash, the bath-rash. The absorption of mineral ingredients from the water of the baths into the system is denied by all the chief authorities. The skin is indeed formed for excretion, not for absorption. No doubt it possesses the attribute of porosity; but the thin layer of the epidermis, smeared with the secretion of the sebaceous follicles, gives sufficient protection against the penetration of any of the contents of the bath under ordinary conditions. The *Medical Gazette* of Lyons recounts a case of arthritis nodosa, in which baths containing two kilogrammes of arseniate of soda, and half a kilogramme of corrosive sublimate respectively, were used without any disagreeable consequences. We can only conceive absorption to be possible when there is some strong external pressure, some pressure at least as strong as that of our atmosphere; and just as water, or even quicksilver, may be forced through wood, so there is no doubt that the idea of forced absorption from mineral baths is a feasible one; and indeed, it is surprising that no attempt at it has been made, seeing that atmospheric baths of the most varied pressure have been for some years in fashion. As, then, there is no absorption, we must consider the injection of the capillaries to be an effect of heat. When this is meant to be considerable, the temperature of the water should be about blood-heat.

The general operation of hot baths is plain enough. The blood is drawn away from the central organs to the peripheral surface, and the pressure on the internal organs is slightly reduced. We can thus see how the most different diseases may be benefited by hot baths, and how hot baths may act as antiphlogistics. By thus deriving to the surface, they act at least as powerfully as leeches or blood-letting.

2. All are agreed that salt baths stimulate the nervous system; but there is difference of opinion as to the way in which this is brought about. Ditterich says that it is by the action on the cutaneous nerves of the salt, or of the warmth of the bath, and by the extension of that stimulus to the central nervous and vascular system. It is a fact that the skin is stimulated; but I think that it is so only by the heat of the water. The cutaneous nerves, as far as feeling goes, recognise no difference between common water and salt water; they recognise only differences of temperature. Beneke, again, says that the general effect of a salt bath is shown chiefly in the transformation of nitrogenous compounds by reflex action, which transformation we can intensify

by the concentration of the bath. We need not quarrel as to the general effect; but Beneke offers no sufficient explanation how this reflex action is brought about. The explanation that I would advance is this; the salt bath acts as a stimulant to the whole nervous system, because it furnishes a good conducting recipient for animal electricity. The electrical organs, *i.e.*, the muscles and the nerves, receive a disproportionately stronger charge of the opposite electricities.

[Dr. Schelle then explains at length his views that the nerves, with their tubules enveloped in neurilemma, may be considered as analogous to the wires and gutta-percha of submarine cables, and the muscles to a Leyden jar; that the rules of working and conduction are the same; that the bath bears exactly the same relation to the body of the bather as the bulk of the earth does to telegraphs; and he thinks that Schiff's experiments on nerves and electricity must for the future be the basis of the theory of the operation of baths.]

But the important question is the practical one: What sort of baths are most favourable to electrical movements? Obviously those which conduct electricity best; and thus, generally, mineral water-baths, rather than those of common water. Comparative experiments have been made as to the conducting power of different mineral waters with delicate multipliers. Pure water is the worst conductor; concentrated solutions are better conductors than weak ones. Chloride of sodium is better than salts of zinc or of copper. The nature of the substance dissolved, as well as the degree of concentration, make a great difference; and this is the explanation how, though there are a hundred waters apparently the same in composition, yet no two act exactly alike, and each has its specific action. This specific action is really electrical, and accounts for the differences and the characteristics of various baths; and explains how artificial never equal natural waters. The physicist discovers differences which neither sight, nor taste, nor smell, nor chemistry can detect.

After the striking facts which we owe to physiologists and to physiologists, there can no longer be any doubt, that a great portion of the therapeutic virtues of baths of mineral waters depends upon electrical conduction, and that, in this respect, salt baths must occupy an important place. As galvanism serves for various curative local processes, so does the salt-water bath for the whole system. It is directed, first, towards the molecules of the nervous system, to force them into that state of polarity, which is the foundation of all healthy nervous action, of innervation as well as of its propagation. Its second action is its electrolytic operation, by which it brings exudations into a state fit for absorption. And it is by no means theory alone that has led me to these conclusions. As to the favourable influence of salt baths, a ten years' experience has given me ample opportunity of studying their effects. I have been especially pleased with the results in numerous cases of neurosis beginning with simple relaxation, and that have gone on to most severe functional disturbances of the nervous and muscular system.

I am far from supposing that I have exhausted the subject of the operation of salt-water baths; but I think that I am doing well in directing attention to electricity, which is more connected with many of our intimate actions and common experiences than we are apt to suppose. Thus it is a common com-

plaint that gutta-percha shoes are unhealthy, and this chiefly owing to their want of porousness. It has been overlooked that they are non-conductors and isolators.

J. MACPHERSON, M.D.

ANATOMY AND PHYSIOLOGY.

WATNEY ON THE MINUTE STRUCTURE OF THE INTESTINAL TUBE.—Mr. Herbert Watney publishes (*Centralblatt für die Medicinischen Wissenschaften*, no. 48, 1874) a preliminary notice of researches on this subject conducted in the Brown Institution, some of which have already been recorded in *Proceedings of the Royal Society* (April, 1874). His results are as follows.

1. In the stomach of the dog, and in the stomach, small intestine, and colon of the rabbit, the nuclei of the epithelia on the mucous surface often show signs of division. There are found, besides, near the base of the epithelium, small round cells, easily distinguishable from the lymphoid corpuscles contained in the epithelium. Finally, there exist intermediate forms between the ordinary epithelia and the above-mentioned small cells, which are arranged in groups of two or three.

2. In the epithelium of the intestinal mucous surface of many animals (monkey, sheep, cat, dog, rabbit), there is a tissue belonging to the connective tissues. This tissue either (a) forms a delicate reticulation with occasional nuclei at the intersections, lying under and between the epithelial cells and extending by prolongations to the free mucous surface, or else (b) is composed of round lymphatic cells. A similar intra-epithelial network is found in the pyloric glands of the stomach and in the Lieberkühnian crypts. The round lymphatic corpuscles of the epithelium are chiefly found in the villi of the small intestine, in the colon, and in the pylorus. The epithelium of the mucous surface covering the tonsils and the lymphoid follicles of the pharynx, as well as the epithelium which crowns the projecting portion of the follicles in Peyer's patches, is infiltrated by a delicate network of nucleated cells, the meshes of which contain lymphatic corpuscles; that is, by a true adenoid tissue which is directly continuous with the adenoid tissue of the underlying follicles. In some parts of the pharynx, this infiltration is so marked that it appears as if the epithelium were wanting.

3. Under the network contained in the epithelium of the intestinal mucous surface, is found a tolerably complete membrane composed of large, pale, flat nucleated cells. The *membrana propria* of the gastric glands and of the Lieberkühnian crypts is continuous with this membrane, and presents the same structure.

4. The epithelium lining the lymphatics of the mucous membrane communicates directly with the adenoid reticulum of the same, and it is easy to show that the endothelial plates of the former are only the transformed connective tissue-cells of the latter.

5. In animals killed during the absorption of fatty matters, the fatty molecules (easily recognised by being stained black with osmic acid) are situated (a) in rows between and around the epithelia of the mucous surface in the small intestine; (b) in the reticulum situated at the base of the epithelium; and (c) as some observers have already noticed, in the connective tissue stroma of the villi, whence they

penetrate into the lymphatics of the villi. We must then suppose that the fatty molecules do not penetrate the epithelial cells themselves, but rather the intra-epithelial network, whence they pass into the network of the villi, in communication therewith, and finally into the central lymphatic, the walls of which are continuous, as before stated, with the network of the villus. Fatty molecules are absorbed in the same manner by the mucous surface of the pylorus, and generally by the glands of the stomach.

6. The network of nucleated cells in the mucous membrane forms a special sheath around the blood-vessels which traverse it, and around the bundles of smooth muscle. The bundles of smooth muscle which pass towards the mucous surface, separate near the surface into muscle-cells, each cell receiving a prolongation of the sheath before-mentioned. In the villi of the smooth intestine, in the papillary projections of the mucous membrane of the pyloric region of the stomach, and in the warty projections of the rabbit's colon, the sheath of each muscular cell appears to communicate with the large pale cells of the subepithelial membrane already spoken of.

7. The vessels of the papillary projections in the pyloric region are surrounded by perivascular lymphatic sheaths, the walls of which are formed by connective-tissue cells arranged in the manner of an 'endothelium.'

J. F. PAYNE, M.B.

TARCHANOFF AND MALY ON THE FORMATION OF THE BILE-PIGMENTS.—Schiff had proved that the liver possesses the property of attracting from the blood absorbed bile-acids injected into the alimentary canal, and again excreting them in the bile. The same property is possessed by the liver with relation to the bile-pigments. According to J. Fürst Tarchanoff (*Pflüger's Arch.* ix. 329, abstract in *Centralblatt für die Medicin. Wissensch.*, no. 2, 1875), the bile excreted in equal intervals of time from a permanent fistula showed quite an enormous increase of bile-pigments, when a solution of hæmoglobin or water was injected into the blood of the animal (dog); on the contrary, a relative diminution in the fixed constituents. It can either be assumed that the liver forms and excretes a large quantity of bile-pigments from the increased supply of dissolved hæmoglobin, or that this transformation has already occurred in the blood, and that the liver, in virtue of an increased attractive property, had only extracted and excreted the colouring matter already present in large quantities in the blood. The latter view is favoured by the fact that, after injection of a solution of bilirubin, the colouring matter of the excreted bile is correspondingly increased. So rapidly and completely does this elimination occur, that neither in the bladder, nor in the urine obtained from a fistula of the ureter present at the same time, could the presence of bile-pigments be proved. A similar experiment had already been made by Feltz and Ritter (*Journal de l'Anatomie et de la Physiologie*, 1870, p. 315) who injected four grammes of bilirubin into the blood of a dog, whilst the author only injected 0.1 gramme. If it be remembered that bile-pigments can be formed in the blood outside the liver, and further that the liver possesses a very pronounced property of absorbing and excreting bile-pigments, then the hypothesis that this pigment is formed outside the liver becomes very probable. The above experiments also show why in hæmatogenous icterus a tinging of the tissues does not occur. As a

symptom of this icterus, an abnormally strong colouration of the faeces is to be observed. Lastly, the author remarks that, after the injection of large quantities of distilled water or weak solution of hæmoglobin, the urine of the bladder as well as of the ureter show Gmelin's reaction in nearly equal intensity, from which it appears that the bladder does not possess the property of taking up and retaining bile-pigments in the urine.

R. Maly writes on the subject in the *Wiener Sitzungsab.*, 1874, Band lxx. 3 Abth., abstract in *Centralblatt*.

1. *Analysis of an Ox-gall Stone*.—Almost one-third of this stone consisted of bilirubin. It contained in 100 parts soluble biliary matter, 18.09; etherial extract, 5.28; phosphate and bilirubinlime, 1.41; bilirubin, 28.1; residue and loss, 47.13. The residue was olive-coloured, contained still some lime with bilirubin, earthy-looking stuffs, and inorganic salts.

According to Maly, bilirubin has the formula $C_{16}H_{18}N_2O_4$; according to Städeler, $C_{16}H_{20}N_2O_5$. Maly has prepared biliverdin from perfectly pure, previously analysed bilirubin, and convinced himself of the correctness of his formula. A further proof of the correctness of Maly's formula lies in the following. When the formation of biliverdin from bilirubin occurs by the simple addition of oxygen, as Maly's formula expresses, then 100 parts bilirubin must give 105.6 parts of biliverdin. By adding the remaining dissolved portion, the author actually obtained from 100 parts of bilirubin, 104.3 of biliverdin, so that there is no doubt of the correctness of his formula.

WM. STIRLING, D.Sc., M.B., Edinburgh.

BRAUN ON THE ELECTRICAL EXCITABILITY OF THE CEREBRAL HEMISPHERES.—Dr. H. Braun, in a recent number of Eckhard's *Beiträge*, gives the results of some experiments he has undertaken with a view of ascertaining the accuracy of Hitzig's statements. He finds, in opposition to Hitzig, that the dura mater is not highly sensitive, even when it has been laid bare for some time. The experiments on the brain were made upon narcotised dogs with feeble induction currents, and were generally confirmatory of those of Hitzig. A new point, however, was the discovery of two centres in the same hemisphere, the irritation of which called forth similar movements. Thus there were two for the muscles of the neck. On irritation with weak currents, not only did muscular contractions take place during the passage of the current, but often subsequent contractions occurred when the current was broken, and these sometimes spread so that the animal became generally convulsed. In regard to the question as to whether the contraction observed in Hitzig's experiments depends upon the conduction of the current through the tissues to distant parts, Braun shows that section of the fibres springing from the vicinity of the irritated surface stops all manifestation of nervous excitation, the movements suddenly ceasing. So also, if the grey matter were sliced away, on the application of the electrical current to the cut surface of the whole substance, *i.e.*, to the ends of the nerve-fibres arising from the cortical substance, the same groups of muscles were thrown into action as when the surface of the grey matter itself was stimulated in this region.

PATHOLOGY.

NOEL ON ENCHONDROMA OF THE BASE OF THE SKULL.—The history and the subsequent necropsy of a very remarkable instance of this kind are related by Dr. Leon Noel (*Annales d'Oculistique*, November and December, 1874). The patient was a man, aged twenty, who had generally enjoyed good health until July, 1873, when he suffered severe pain around the left orbit, which lasted for three days without impairing his sight. In the following September he became giddy, the pain returned and he found his left eye had become blind, and at the same time that the right eye was affected. He also heard noises in his ears. The patient's previous history threw no light upon the nature and the cause of these symptoms. On the right side the eyelids were swollen, and their veins were much dilated; the eyeball was pressed forwards, and was barely covered by the eyelids, being almost immovable; the conjunctiva was chemosed and the pupil dilated and sluggish; the intraocular tension was slightly increased, and the vision reduced to $\frac{1}{40}$. The media were transparent, but the optic disc was cloudy and ill defined, and the retina around it was infiltrated; the arteries were small, but the veins were tortuous and engorged. No tumour could be detected within the orbit; there was a good deal of pain at times in the branches of the fifth nerve. On the left side, the condition of the eye was much the same, although to a less degree; but the optic disc on this side was white and atrophied, and there was no retinitis. There was no appearance of pulsation around either eye. On the right side the patient heard a murmur isochronous with the pulse, but no murmur could be detected with the stethoscope; the hearing was impaired on both sides but more so on the right than on the left side. Smell was entirely abolished, and the nasal fossæ were filled with puriform mucus, so that air could only pass with difficulty, but otherwise nothing abnormal could be detected in the nasal cavities. The patient complained of want of taste; but when he was quite blind, it was clear that he could well distinguish the different flavours of various kinds of foods. With the exception of pains in the frontal region, the patient had no impairment of sensibility or of motor power anywhere else than as regarded his eyes. The diagnosis was that a tumour of some kind had formed at the base of the skull, but was situated outside the brain and its membranes. The progress of the case was shortly as follows. At first there was an amendment in all the symptoms, soon followed, however, by complete blindness in the right eye, and by increased displacement of both eyes forwards. In a short time, there was increase of pain, and a firm elastic tumour was now felt at the inner aspect of each orbit. The tumour increased steadily, and the exophthalmos became extreme, on each side; and there was anæsthesia of the region supplied by the second division of the fifth nerves; the cornea of each eye became opaque. In April, 1874, the soft palate had become displaced by a tumour behind it. During the next three months the patient was unable to take much food, and became very feeble; but there was no loss of intelligence or of motor power. On October 16, 1874, he died, rather suddenly, just ten months after his admission and eighteen months after his first seizure with pain.

Necropsy.—A semitransparent and nonvascular tumour completely filled both orbits; it bulged into the pharynx, into the left pterygo-maxillary fossa, and into the nasal cavities. On removing the brain, the tumour had involved the base of the skull from the crista galli to the occipital foramen; it projected backwards into the posterior fossa so as to compress the medulla oblongata. The middle fossa was entirely filled by the tumour, and the sphenoid bone was no longer visible. The brain presented a deep excavation on its under surface, but its substance was unchanged generally speaking; around the olfactory bulbs, however, it had become softened. The pons Varolii was small and flattened. The medulla was flattened and compressed to a remarkable extent, but its tissue was unaltered; it is probable that compression of its substance was the immediate cause of death. The olfactory nerve on the left side was natural; but that on the right side was softened, and could not be distinguished from the softened brain-tissue around. The optic commissure was flattened and hardly recognisable. The right optic nerve was unaltered; but the left nerve was flattened and gelatinous. The third, fourth, and sixth nerves, in their intracranial portions, were natural, but were soon lost in the substance of the tumour. The fifth, though involved in the tumour, could be traced forwards to some considerable extent.

In its structure, the tumour was nonvascular and generally soft, its firmest portions being in the orbits, a large portion of it being gelatinous in consistency, and in one or more places containing cysts of irregular size. Under the microscope, the structure was that of hyaline cartilage.

The case is of great interest, in showing as it does the great extent to which the brain-substance will admit of pressure, provided it be gradual, without any impairment of intelligence or of general motive power.

BOWATER J. VERNON.

DURET and CARVILLE ON OLD SOFTENING OF THE BRAIN IN A DOG.—Chance brought under the notice of MM. Duret and Carville a fact in comparative pathology, which will have a great effect in the discussion of the question of the existence of motor centres. They were seeking in a dog, whose brain had been partially uncovered, the phenomena produced by electric excitement of the cortical layers, specially those assigned by Ferrier to the motor centre of the limbs. Notwithstanding the employment of powerful currents, they did not observe any marked phenomena; on this occasion, the irritation of the grey cortex of the brain produced no results whatever, for the reason that nature had produced a lesion which the most skilful experimenter would find it very difficult to repeat. There was in the animal a focus of old softening which had destroyed the centrum ovale of Vieussens, the peduncular expansion above the corpus striatum, leaving the corpus striatum itself intact. The dog, however, had no hemiplegia, nor any perceptible difficulty, either in standing or in walking.

SAVORY ON TUBERCULOUS TESTIS.—Mr. Savory, in a clinical lecture reported in the *Lancet*, of Jan. 30, calls attention to the loose way in which the term 'tuberculous' is applied to cases of chronic inflammatory disease of the testicle. The majority of these cases have no connection whatever with tubercle, but are the result of chronic orchitis, frequently of syphilitic origin, and what is mistaken

for crude tubercle is really cacoplastic lymph and inspissated pus. The diagnosis of true tubercular disease from that which is erroneously so called by mere examination of the organ, even after its removal by operation, is often difficult; the history of the patient and his general constitutional state are far more reliable guides. But it is of great importance to make the distinction, since the treatment depends upon the diagnosis; in one case mercury and discutient applications would be beneficial, and in the other highly injurious, to the patient.

J. W. LANGMORE, M.D.

MEDICINE.

EISENLOHR ON ULCERATIVE ENDOCARDITIS AND MICROCOCCUS-EMBOLISM.—Dr. C. Eisenlohr records a case of this kind which occurred in Professor Friedreich's clinic at Heidelberg (*Berliner Klinische Wochenschrift*, 1874, no. xxxii.). The real nature of the disease was not discovered until after death.

The patient, a labourer aged fifty-eight, was under treatment in the hospital for the last five days only of his life. At his admission, he was able to give a short but very imperfect account of himself. He had been an habitual drinker, had suffered for weeks from bronchitis, but had been able to work until quite lately. Fourteen days before, he had been suddenly seized with retention of urine and pain in the region of the bladder and loins; the catheter had to be passed frequently. Thereupon there had supervened disturbance of the general health, anorexia, nausea, and headache, diarrhoea, a feeling of oppression and heavy pain in the chest, and increased cough. During the last few days, the retention of urine had disappeared. When first examined, the patient was somewhat cachectic and sallow, and especially remarkable for his manner, which was sometimes restless and talkative, at other times more apathetic. Physical examination revealed general bronchitis; slight enlargement of the heart with weak impulse, dull sounds, and no bruit; and nothing remarkable about the abdomen. Urination was normal; the urine, 1010, slightly albuminous, with a deposit of pus, epithelium and several granular casts; the catheter was passed easily, and there was no evidence of urethral stricture. The patient complained chiefly of tightness of the chest and of the cough and difficult expectoration. The sputum was mucoid, without blood. The temperature at night was 101.5°, and the pulse 112, small and soft.

From first to last there was little change in the physical signs. On the night after his admission the patient was delirious, and passed his motions and urine in the bed; there was moderate diarrhoea. Next day consciousness was more deeply affected, and the heart weaker. On the third day these symptoms increased, diarrhoea continued, and on the sixth day the patient died after a period of complete unconsciousness. The temperature, after the first evening, was as follows:—Second day, morning, 100.4°, evening, 102.8°; third day, morning, 100.8°, evening, 103.7°; fourth day, morning, 102.2°, evening, 103.7°; fifth day, morning, 102.2° evening, 101.5°; sixth day, morning, 103.7°. On the same occasions respectively, the pulse was—104, 104; 88, 116; 108, 120; 120, 124; 140.

Twenty-four hours *post mortem*, the following con-

dition was found. The heart contained liquid lake-tinted blood; the myocardium was very flabby. The right aortic valve and both flaps of the mitral presented ulcerated spots covered with decolorised fibrin. The lungs were œdematous; the pulmonary arteries normal. The spleen was very large, and contained a single metastatic focus. The kidneys contained many small abscesses of various sizes. The liver presented a few clear yellow points; it was moderately congested, and somewhat dull in appearance. In the jejunum a single rather large ulcer was found, with a peculiarly brownish-red surface; in the transverse colon there were also yellow points of various sizes, with a hyperæmic zone. The bladder was not remarkable. In the membranous portion of the urethra there was found a breach in the wall, leading into an ulcerated cavity about the size of a nut; the latter contained an opaque brown thickish fluid. The prostate was not enlarged. In the cranial cavity two small hæmorrhages were found, in connection with the meninges; one of them communicated with a cavity as large as a nut in the extremity of the left posterior cerebral lobe, which was filled with a fresh blood-clot, and had irregular friable walls. Smaller hæmorrhages were scattered over the pia mater of both hemispheres; some of the spots contained a prominent central yellow point.

The various organs were subjected to very careful microscopical examination. The myocardium of the left ventricle presented abundant micrococcus colonies, in the form of rounded and tubular masses. In the liver, lung, and altered spots of the pia mater, no micrococci could be discovered. The microscopic appearance of a section of the diseased cardiac valves is described as very striking, unquestionable micrococcus colonies being seen situated between the fibrillar elements. These colonies presented the appearance of rounded balls of a countless number of minute highly refracting granules embedded in an opaque substance, exactly corresponding with previous descriptions, e.g., of the *Zooglyphen* of Billroth. By the apposition of such rounded masses there were formed sausage-shaped or tube-shaped structures, which were sharply defined and of somewhat considerable size. The yellow spots described as found in the transverse colon presented the clearest evidence of the embolic nature of these changes. Here a fortunate section revealed a very small artery, filled with a whitish mass, which consisted of innumerable coccus-heaps between red and white blood-corpuscles.

Eisenlohr concludes that the *fausse route* in the urethra must be considered the starting point of the infectious process in this case, although it was certainly a very insignificant local change. Very probably the septic matter absorbed from this source induced the ulcerative process in the cardiac valves; embolism was the secondary result in the situations described. The other alterations within the cranium were also of interest.

The author declines to express any decided opinion on the relation of the micrococci to the local and general disturbances in this case. He refers briefly to the investigations of Wagner, Leube, W. Müller, Burkart, Winge, Heiberg, and Billroth, on this subject, and concludes that it is most advisable to consider with Virchow the local process as diphtheritic (*diphtheritisch*) without prepossession by any parasitic theory.

BECKER ON PARACENTESIS IN SERO-FIBRINOUS PLEURISY; ITS INDICATIONS AND VALUE.—Dr. L. Becker, of Munich, discusses this question, and records an illustrative case (*Berliner Klinische Wochenschrift*, 1874, nos. 41 and 42). He mentions the great variety of opinion which at present prevails on the indications for aspirating a pleural effusion—from the one extreme of operating only as a vital necessity, to the other of applying this method of treatment in every case of pleurisy so as to shorten the process and facilitate resorption.

The author begins by glancing at the pathology of inflammation of the pleura. Hyperæmia, shedding of the epithelium, fibrinous exudation, effusion, compression of the lung, and formation of vessels in a 'false membrane' are the successive steps of the process. From the capillaries in the false membrane there occurs effusion, and perhaps hæmorrhage. But when the pressure within the pleural cavity has reached that of the vascular system, an endosmosis takes place, and the hyperæmia declines on account of the compression of the vessels in the root of the lung. The 'false membrane' becomes connective tissue and contracts; the newly formed vessels perish; more fluid is absorbed; the fibrin undergoes fatty degeneration; and adhesion and healing follow in due course. The process is somewhat different when the products are purulent, but no sharp distinction can be drawn between acute and chronic pleurisy.

An answer may now be offered to the question whether removal of part of these inflammatory products will promote healing. Dr. Becker replies by considering several cases. 1. Sudden and abundant pleuritic effusion may cause extreme dyspnoea by diminishing the pulmonary surface, e.g., in the event of previous circulatory disturbances; the brain may then become œdematous, and the heart may be dangerously compressed, and its substance affected. The author allows that paracentesis is here demanded; there is a vital indication to relieve the condition by any possible means. 2. The heart may be displaced, but the pulse and respiration may remain good. How far will removal of part of the fluid aid resorption if effusion have reached its limit, or resorption have begun? The lung will return so far; circulation is restored in the vessels of the pulmonary pleura; friction is again set up: in short, all the conditions of transudation into the pleural cavity are re-established, and it returns. The previous pressure is restored; the system has been drained of albumen and salts; and the condition of the heart is as before, or even more serious. 3. The lung may be already adherent when the operation is undertaken. After a time the fluid will not flow into the aspirator, the tube collapses, and air enters the pleural cavity. That this accident happens, is proved by the fact that pneumothorax is frequently so developed; as well as by the experiment of aspirating a tightly corked bottle into which air will afterwards be found to have passed. But pneumothorax is not the only evil effect of aspirating the chest when there are adhesions; the pulmonary alveoli suffer dilatation; the lung becomes congested; and bronchitis, hæmoptysis, and pneumonia may follow. For all these reasons, Dr. Becker argues that it is better to leave the fluid alone and allow nature to effect the cure. Besides, it is not comprehensible how partial removal of the fluid shall facilitate the resorption of the remainder. There are yet other reasons for not operating: marasmus is not prevented

by fresh pleurisy; neither is the risk of sudden death, which depends upon fatty degeneration of the heart. And the more frequent the aspiration, the more probable is the occurrence of empyema.

Dr. Becker's case illustrates the preceding points very well. A woman, aged thirty-two, was found to be suffering from well-marked right pleurisy with abundant effusion; she had been ill for a fortnight. The temperature was 99.5° , the pulse 130, and the respirations 50. Dyspnoea was extreme, faintness supervened upon any movement, and swallowing was very difficult and followed by suffocative attacks. There were, further, both symptoms and signs of slight left pleurisy. Here the indications for thoracocentesis were vital, and 614 cubic centimètres of slightly red fluid were removed at once by the aspirator: the lung expanded a hand's-breadth, the patient was relieved, and the respirations fell to 30. But during the operation the sputum became tinged with blood; the tube collapsed after a time, and the operation was interrupted. Immediately afterwards, signs of circumscribed pneumothorax were discovered. Two days after the operation there was evidence of bronchitis and of return of the pleuritic effusion; and on the fourth day the symptoms were again so urgent, that aspiration was repeated and 456 cubic centimètres of fluid removed, of which about a third was blood. Considerable relief was given, but only for a few hours; and the patient died the same night of suffocation and exhaustion.

Post mortem, a large quantity of air was found in the right pleural cavity, and a bloody serous effusion filled the rest of the space. The lung was perfectly compressed; an old adhesion existed posteriorly between the upper part of the inferior lobe and the chest-wall. The lung had not been wounded.

Dr. Becker points out that in this case the operation was followed, not only by pneumothorax, but by congestion, as was manifested by the hæmoptysis, bronchitis, and hæmorrhage into the pleural cavity.

SURGERY.

NICOLADONI ON DUMREICHER'S METHOD OF TREATING UNUNITED FRACTURE.—Dr. Carl Nicoladoni, of Vienna, reports in the *Wiener Medizinische Wochenschrift*, no. 5, 1875, two cases of threatening failure of union in fracture of the tibia, in which Dumreicher's method was carried out with complete success. On the supposition that delayed and faulty union are due to deficient vascularisation and a faulty supply of nutritive material at the seat of fracture, this method is practised for the purpose of artificially producing a persistent hyperæmia of the parts at the seat of injury, so as to set up here a constant irritation of all the tissues, and at the same time to afford to these irritated tissues a constant and excessive supply of nutritive material. The injured leg, in which there is a tendency manifested to the formation of a false joint, is enveloped from the toes to a part a little below the fracture by a strong flannel bandage. Four wedge-shaped pads are applied, two above and two below the fracture, in such a manner that the broad ends of the upper and lower pairs are opposed to each other, and that between them a free surface of skin is left which corresponds to the seat of fracture. These pads are kept in position by strips of adhesive plaster, and covered by a thin wooden splint, over which a bandage is firmly applied. The whole limb is then kept at rest on an ordinary splint. By the application of the bandage below the fracture, the peripheral portion of the limb is protected against the injurious results of pressure made by the pads above the ankle. The pressure of the lower pads and of the flannel bandage induces an active arterial hyperæmia of the parts about the false joint, which hyperæmia is more or less restricted to these parts, as the two pads are so applied as to retard the backward flow of venous blood, though not interfering very much with the arterial supply. After an application of this apparatus for twenty-four hours, the skin becomes red and hot, and the fractured portion of bone can no longer be felt, on account of the swelling of all the superjacent soft parts. This swelling is firm and differs altogether, according to Dr. Nicoladoni, from ordinary œdema. On the second and third days, the parts between the wedge-shaped pads become more swollen and firmer; but this swelling will speedily disappear on the removal of the pads, and will not persist and do any good until after the apparatus has been retained for five or six days. In favourable cases, after an application kept up, with occasional short intervals, for three or four weeks, the fragments become much less movable, and cannot be examined and moved without much pain. The limb can now be placed in a firm apparatus of plaster of Paris or water-glass, and in a few weeks the fracture will become firmly consolidated. In the first case reported by Dr. Nicoladoni, the pads were applied during eight weeks, with occasional intervals of rest, lasting for two days. A gypsum bandage was then applied, and at the end of the tenth week the fragments of tibia were found to be firmly consolidated. In the second case the pads and bandages were applied during a period of two months; six weeks after their removal and the application of a firm bandage, there was perfect union.

Dr. Nicoladoni reports also in this contribution a case of double abscess of the tibia treated by opera-

tion, in which a sluggish condition of the granulations and retarded healing in one of the exposed cavities in the bone were overcome by applying the above-mentioned apparatus of pads and bandages. This case is cited in order to prove that Dumreicher's method, where successfully applied in cases of delayed union of fracture, acts not merely by causing irritation of the periosteum and by setting up an highly productive periostitis, but also by stimulating to osseous outgrowth the whole thickness of the bone just above and below the seat of fracture.

W. JOHNSON SMITH.

COURTY ON THE TREATMENT OF ANAL FISTULA BY THE ELASTIC LIGATURE.—In a clinical lecture delivered at the Hôtel-Dieu, Saint-Eloi, Professor Courty, of Montpellier (*Bulletin Général de Thérapeutique*, January 30, 1875) highly extols the use of the caoutchouc ligature for deep and extensive rectal fistula. For years, he says, he has in all bad cases avoided the knife, believing that considerable danger from bleeding is incurred at the time of operating, and also afterwards, especially when the case is complicated by the existence of internal hæmorrhoids; there is also an additional source of danger, a large suppurating surface is left which is liable to erysipelatous inflammation, and may give rise to phlebitis, purulent infection, etc. Another objection to the wound made by incision is, that it requires much and constant dressing, to obviate the tendency to the formation of a new fistula by the growing together of the divided parts, which dressing is alike troublesome to the surgeon and painful to the patient. These, among other considerations, have induced Dr. Courty to prefer the linear écraseur, or the 'ligature ulcérate,' and with both of these he has met with considerable success; nevertheless, these methods have their disadvantages. The operation by the écraseur is excessively painful, and so is the ligature, either of thread or wire, as it has from time to time to be tightened; these and other objections are entirely removed by the adoption of an India-rubber ligature; when this is passed through the fistulous track and securely knotted, Dr. Courty says he considers the surgeon's work is really ended, scarcely any supervision is required, and no dressing needed; all that is necessary is to keep the part clean, and the patient may inject into the fistulous passage from time to time a lotion of coal-tar or carbolic acid. All Dr. Courty's patients have done remarkably well. There has been no hæmorrhage; the pain has been but slight and easily controlled by sedatives; many patients after the first day did not keep their beds, but walked about the chamber and even went out of doors; and no secondary accident has occurred, the wounds healing with great facility. To lessen pain at the operation and give ease after it, Dr. Courty directs his patients to take every hour (commencing some hours before the operation) small doses of morphia and chloral alternately; this is continued until all the pain subsides. The ligature comes away in from six to eighteen days, the most usual time being nine days by which time the wound is generally nearly cicatrised. Dr. Courty prefers the tubular to the solid India-rubber, the former being, in his experience, of more uniform strength and less liable to fracture.

W. ALLINGHAM.

VOLTOLINI ON A PIECE OF NUTSHELL LODGED IN THE LARYNX FOR TEN MONTHS.—Voltolini (*Berliner Klinische Wochenschrift*, February 8,

1875), relates the case of a boy, ten years of age, who was playing with his schoolmates without paying attention to a piece of nutshell he had in his mouth at the time. Suddenly he was seized with dyspnœa, in consequence of which tracheotomy had to be performed. The boy soon got better, so that the tracheal wound was allowed to heal. He could speak and sing, and did not complain of pain. One night, having retired to bed without any premonitory symptoms whatever, he was aroused from his sleep by a very intense attack of dyspnœa. It was then found necessary to again dilate the tracheal wound. A foreign body was looked for in the larynx, but five surgeons could not find any. In the mean time the boy began to complain of burning pains in the larynx, and his attacks of dyspnœa returned, whenever an attempt was made to remove the cannula. This state lasted for ten months. Voltolini, however, was convinced that there must be a foreign body in the trachea, and he invented an instrument for the better illumination of this (for the description of which the reader is referred to the original). Voltolini discovered then a brown hard body situated at the posterior wall of the trachea. It was firmly impacted there, and could only be removed with some force. It was a piece of nutshell, fifteen millimètres long and ten millimètres broad, so situated with the convexity towards the posterior wall of the trachea, that the concavity allowed the passage of the cannula.

SYPHILOGRAPHY.

LEWIN ON INFECTIO SINE COITU.—Dr. Lewin brought before the Medical Society of Berlin (Pick and Auspitz's *Vierteljahrsschrift für Dermatologie und Syphilis*, 1874) some instances of syphilis communicated through kissing, suckling, and inheritance, which illustrate several important points in the natural history of the disease. In the first group of cases were two women and their children. One woman had an indurated scar on the lower lip, and a maculo-papular eruption of the body. She had noticed in the seventh month of her pregnancy a pustule on her lower lip; having also for some time previously remarked that her husband had sore lips. This pustule left a hard scar. The child, born prematurely, had several spots and small ulcers on the skin, and gummous orchitis. The second woman,

having given birth to three healthy children, was infected by suckling a syphilitic child. She had a hard sore on the right nipple and constitutional syphilis. Lewin holds that these cases establish, among other better known facts in the natural history of syphilis which he enumerates, certain points less generally admitted, viz., that a woman, even when infected in the latter months of pregnancy, and suffering only from early secondaries, may give birth to a child who presently shall have a tertiary form of the disease; and again, that tertiaries do not need mercury for their production. The next proposition he laid down was, that the symptoms of inherited disease which manifested themselves at birth may disappear without any treatment. The disorder may then become latent, and break out again several years later. [Though this is doubtless a correct statement, Lewin does not adduce any evidence in this paper to confirm it.]

In the following group, a woman with a child at the breast, by giving suck to a syphilitic child, was inoculated herself, and subsequently infected her own child and her husband. The husband died not very long afterwards from cerebral affections, which the *post mortem* notes proved to be syphilitic. The woman was married to a second husband, who never had syphilis, notwithstanding that his wife had frequently syphilitic affections of the pharynx and larynx. Two children resulted from the second marriage, making her offspring three. The child of the first marriage, who had acquired syphilis at her mother's breast, was treated with mercury, and the symptoms disappeared. Nevertheless, she must have had further troubles, for when examined there were found scars and adhesions of the soft palate and a notch in the epiglottis. She, moreover, has suffered from her sixteenth year from lupus of the thigh, and periostitis of the os frontis and tibia, continually relapsing. At seventeen she married a man not previously syphilitic, who died a year and a half afterwards from tubercular meningitis. A premature child was born, who lived fourteen days. Two years later she was married again, and has now a child seventeen months old, who has scrofulous lichen and a gummy ulcer of the thigh. To continue the history of the children of the second marriage of the first woman; one died of syphilis at five and a half months; the other, now a girl aged thirteen, was healthy till her sixth year, when syphilitic eruptions appeared which continued for five years. This family is a striking example of the long duration of the syphilitic poison, and how deeply it penetrates into the organism. Further, one of these cases shows that a child may inherit syphilis which will not become apparent for several years subsequently to birth. Probably many cases of ulcerating skin-disease, especially lupus, are really manifestations of syphilis. Lastly, that hereditary syphilis can be derived solely from the mother is also clearly shown by these histories.

BERKELEY HILL.

MATERIA MEDICA AND THERAPEUTICS.

KARNER ON THE USE OF CHOCOLATE IN CHRONIC INTESTINAL CATARRH.—A series of articles from the pen of Dr. Karner have lately appeared in the *Allgemeine Wiener Med. Zeitung*, in which he

shows the value of this substance as an article of food. He refers especially to its use in chronic intestinal catarrh, and cites, among others, the following typical case of chronic catarrh of the intestines to illustrate its action in the simplest manner: 'Rosalia M., aged seventeen months, poorly developed and nourished, suffered from intense meteorism, numerous thin, fluid, feculent discharges, which alternated from time to time with normal stools. There was considerable emaciation, and the child also had intertrigo, of which there were frequent relapses. The diarrhoeas could be attributed only to poor nourishment. After strictly regulating the diet, small doses of Dover's powder and acetate of lead were first administered, and in three days were substituted by the chocolate, of which a cupfull was given daily. A dessert-spoonfull of the powder sufficed for a cup of chocolate. The mother was also instructed to allow the child as little fluids to drink as possible. The result was astonishing. The discharges decreased in number day by day, the weight of the child rapidly increased, and after a few weeks it had perfectly recovered; a remarkable change for the better was observed in its bodily development, and the intertrigo had not recurred.'

Such cases of chronic intestinal catarrh admit of no experimentation, as the physician is usually called at a time when the symptoms of disease have already assumed a threatening aspect. 'By this diarrhoea,' says Niemeyer, 'the previously healthy, well nourished child is at first but little affected; but some fatal judgment often asserts it to be a safety-valve that protects the child from convulsions during teething, and that must not be stopped. Hence it often happens that the doctor is not called till the child has become flabby and relaxed, and then it is frequently difficult to master the disease; the diarrhoea continues, the child emaciates more and more, and a large number of children die during their second year from chronic catarrh of the intestines.'

GUBLER ON THE ACTION OF CONICINE ON CUTANEOUS SENSIBILITY.—M. Gubler, in the *Bulletin de Thérapeutique*, for January 30, 1875, in the first instance relates facts showing that hemlock modifies sensibility, and specially points out the well-known phenomena of the death of Socrates, and the case recorded by Hunter, in which a man who had taken a large dose of hemlock lost the power of using his fingers. He goes on to relate a circumstance lately observed by him, in which this action on sensibility was of the clearest nature. A lady applied some conicine ointment with the fingers of her right hand to a cancerous tumour in the region of the liver, under which her husband was suffering. After some time the fingers with which she was rubbing the tumour, lost all feeling; she then changed the hand and used the left hand with a glove on, but again all sensation left the fingers. These phenomena disappeared quickly so soon as she left off using the ointment. M. Gubler lays stress on this fact as an evidence of the reality of the modifications produced by conicine in sensibility, a proposition already laid down by him in his commentaries on therapeutics.

PRÉVOST ON APOMORPHIA.—In the *Bulletin Médical de la Suisse Romande* for November, 1874, Dr. Prévost reports a case in which the subcutaneous administration of from three to four milligrammes of apomorphia in a woman attacked by angina compli-

cated with gastric troubles, produced a disquieting collapse and a tendency to syncope, which lasted from a quarter of an hour to twenty minutes, during which time the pulse could scarcely be felt, and the pupils were dilated. In this case, the usual vomitings appeared in about five minutes and were several times repeated. The patient fell into a profound sleep, which lasted about half an hour after the phenomena of collapse. The following day the patient was in a satisfactory condition, the vomiting having markedly improved her condition. It is a question whether in this case the state of collapse should be attributed to the mere effect of the sickness, or to the account of the apomorphia, though that was administered in very much smaller doses than is usual (one centigramme). M. Prévost refrains from pronouncing any opinion on this point. Bearing in mind the cases of collapse observed by Harnach, he recommends prudence in the administration of this drug.

OBSTETRICS AND GYNÆCOLOGY.

DAX ON THE EFFICACY OF BLOOD-LETTING IN THE OBSTINATE VOMITING OF PREGNANCY.—In a letter addressed to Professor Courty (*Archives Générales de Médecine*, January, 1875) Dr. Dax calls attention to a mode of treatment suggested in a periodical called *Agenda-Formulaire*, for 1874, under the head of vomiting; cauterisation of the cervix (?), induction of abortion (?).

Because pregnancy is the cause of the sickness, its arrest, it is said, cures the disease. In other words, to save the mother kill the child. As this manual is chiefly consulted by young practitioners, Dr. Dax warns against the adoption of the precept by inexperienced beginners, both on the score of its criminality and its danger, and advises in its stead bleeding; and in doing so, reviews the various opinions of this mode of treatment, held by several leading authorities.

Mauriceau, in his *Traité des Maladies des Femmes Grosses* (liv. 1, p. 109) recommends bleeding as very efficacious, and thoroughly indicated in cases where purgatives and other means have failed, and the sickness imperilled the life of the mother and child.

Chailly-Honoré counselled leeches to the epigastrium, if from the effects of vomiting this region were tender and painful; and general bleeding, above all, if the pain radiated into the loins and the hypogastrium. This treatment is rather intended by him to check and prevent abortion, than vomiting, which latter is treated by anodynes, emollients, etc. Burns, on the contrary, in his *Traité des Accouchements*, advises bleedings against distressing sickness, abstracting blood in proportion to the strength, vigour, and plethora of the patient and the state of the pulse; he states that, 'the universal testimony of accoucheurs and his own experience fully convinces him of the desirableness of this practice.'

Hefeland, in his valuable *Manuel de Médecine Pratique*, recommends, against excessive vomiting of pregnancy, 'bleeding, above all bleeding.' Professor Delmas opposed bleeding in obstinate sickness of pregnancy; whereas Alphonse Ménard bled, and did not at all regard it as an intractable affection. In a memoir published in the *Transactions Médicales* (May, 1831) in reply to the question 'which are the diseases to which pregnancy gives rise, which it cures, and which are those whose impetus

of progress it arrests?' he states that, 'bleeding should be general, local, in order to be employed here with effect. It is not essential that a state of plethora should be pronounced to practise the first—it often suffices that gastritis does not exist. I have frequently seen,' the author says, 'the most violent vomiting at all stages of gestation yield to the opening of a vein, in women of divers temperaments and of unequal strength.'

M. Dax gives a brief account of the results of five personal observations.

1. In 1844, a lady, pregnant for the first time, at the third month suffered from continued vomiting and nausea, which nothing relieved. She was bled to about three and a quarter ounces, and kept in a horizontal position for a couple of days and on a spare fluid diet. By the third day she was up and about; could eat well, and the sickness entirely disappeared. She was delivered at full term.

2. Madame P. (1855), who believed herself six weeks pregnant, vomited up to midday; less in the evening, and sometimes not at all. Treatment for fifteen days with anodynes, enemata, etc., made her worse rather than better. She was of an exceedingly nervous temperament, and was with difficulty persuaded to be bled. She was treated as in the previous case. On the fourth day she got up, and did not vomit again.

3. In October, 1863, M. Dax was consulted in the case of a primipara, pregnant four months, who had not ceased from vomiting since the commencement. She was attenuated, pale, thin, feeble, and very nervous. M. Dax advised repose, pastilles de Vichy, etc., with no amelioration at the end of eight days. Opium was ordered to be given, and the same treatment continued. She was no better, but vomited everything, and was anæmic to the highest degree. She was bled to between three and four ounces. The same after-treatment was followed as in no. 1. By the third day there was slight retching; no food was returned. From this day she could get up, and all vomiting ceased. She went her full term.

4. Madame S. (1872), a multipara, pregnant three months, had miscarried previously at seven months. When seen she was very pale and very thin, suffered in the kidneys, was continually sick, and had no sleep. She was ordered to bed without benefit. She was bled to the extent of about three ounces and a half, vomited no more, and was able to sleep two hours. At the end of fifteen days she could get up, walk, sleep, and eat. She had no return of the sickness, and was confined at full term.

5. In September 18, 1874, M. Dax saw Madame Ch., who suffered from the kidneys. She had borne once, and was pregnant between three and four months. She was continually sick. He took away about three ounces and a half of blood, and advised rest in bed and a spare diet. No sickness returned. What was most remarkable was, that the ascitic fluid, which was considerable in the peritoneal cavity, entirely disappeared, and the patient, he was led to believe, continued well, and gestation proceeded normally.

In Case 3, the peril to mother and child was extreme. The danger to mother and child by this treatment is imaginary—it saves both.

In conclusion, the author remarks that, although he believes he has conclusively proved the efficacy of bleeding, still he advises the trial of the ordinary remedies—ice, opium, effervescing drinks, baths, change of air, exercise or rest, choice of diet, and all

the other known hygienic and therapeutic agents; these in many cases suffices, but in extreme instances no remedy is so powerful as bleeding.

W. C. GRIGG, M.D.

BIZZOZERO ON A CASE OF DISSECTING PHLEGMONOUS PERIVAGINITIS.—At a recent meeting of the Turin Medical and Surgical Society (*Gazzetta delle Cliniche*, February 2, 1875) Professor Bizzozero related a case of dissecting phlegmonous perivaginitis, accompanied with prolapse of the vagina and of the vaginal portion of the cervix uteri, and ending in recovery.

The patient was a woman, aged thirty-eight, of fairly good physical constitution: she had had sexual intercourse rarely, and had never suffered from blennorrhagia. On her admission into hospital under the care of Professor Timermans (in February, 1869), her most prominent symptoms were: temperature, 104° Fahr.; pulse, 96; headache; symptoms of bronchial catarrh; ardent thirst; loss of appetite; constipation; and pain in the lower part of the abdomen. These symptoms lasted several days, and to them was added difficulty in micturition, which rendered the use of the catheter necessary. On the tenth day after admission, she had ardor urinæ and tenesmus; there were superficial abrasions on the labia majora and minora, extending to the orifice of the vulva; the contact of the urine with these parts produced very acute pain. On the twelfth day, while she was being examined, there escaped from the vaginal cavity a body which, on examination, Dr. Bizzozero recognised as the vagina itself with the vaginal portion of the cervix uteri. It had the form of a sac (the vagina), the fundus of which was thickened (vaginal portion of the uterus) and perforated (external os uteri). Towards the outlet, the walls were thin; the outline of the sac was rather irregular. The vaginal portion of the neck of the uterus was separated from the vagina for about half its circumference. The external surface was rugose, rather soft and spongy; the inner surface was smoother and more compact, though somewhat irregular. On microscopic examination, it was found that the connective stroma of the part was in good preservation. The vessels were partly empty, partly distended with red matter derived from the decomposition of blood, which presented masses of vibriones and bacteria. The latter were also found in great abundance in the loose perivaginal connective tissue, more scantily in that which formed the stroma of the vagina. All trace of vaginal epithelium had disappeared. In the mucous membrane of the vaginal portion of the neck of the uterus, there could still be discerned the large vessels running perpendicularly to the surface of the membrane, as described by Henle.

This elimination of the parts was followed by extensive perimetritis. Gradually, however, the patient's condition improved: the discharge diminished and became less offensive; and, a month after admission, the patient left the hospital. Two months later, the ostium vaginæ was found to be normal; there was little vaginal discharge. The finger reached the cervix uteri with much difficulty, after passing through a hard resistant fibrous ring like a hymen. With the speculum, this ring could be seen to lie before the cervix. No mucous or purulent discharge was observed. An attempt was made to procure dilatation by the use of prepared sponge; it promised at first a favourable result, but

had to be desisted from on account of an attack of acute arthritis.

Dr. Bizzozero says that there are only three recorded cases of this malady; two, by Marconnet of Moscow, ending in recovery; and one, by Menkenitsch of Tiflis, which terminated fatally.

A. HENRY, M.D.

PSYCHOLOGY.

THOMPSON ON GENERAL PARALYSIS OF THE INSANE.—Dr. George Thompson contributes to the *Journal of Mental Science* (January, 1875) a paper on the Physiology of General Paralysis of the Insane. He refers to certain sphygmographic tracings of paralytics made by him at the West Riding Asylum, and depicted in the first volume of the Asylum Reports. On these chiefly he founds his theory of general paralysis. He is of opinion that the organic change which exists in the very early stages of general paralysis consists of a diminished calibre of the vessels, which is of the nature of a persistent spasm; also that this spasm, persistent if left untreated, is, if recognised early, amenable to remedial means, and that the lesions found after death are not the cause, but the result, of early organic changes that need be only of temporary duration. He found that the tracing of the pulse at the wrist of paralytics, when untreated, is precisely similar to that found in a person in good health, who had been exposed to a cold bath for the space of one minute. The vessels of the retina and optic discs are thin and attenuated, and the discs themselves void of their natural pink tint. General paralytics, he remarks, are more frequently the subjects of cerebral syncope than persons labouring under any other disease of the brain; and in the early stages of general paralysis, the temperature of the body is lower than in health, and the skin of the patients is in the condition known as cutis anserina, resembling that seen in the cold stage of ague, in cholera, or in rigor. He contends that, by the administration of remedies known to be antagonistic to spasmodic action, the pulse-tracing may be brought back to a healthy form, and the retina and temperature likewise restored to the normal state. Dr. Thompson bases his theory of persistent spasm on the uniform appearance obtained in the pulse-tracing in the early stages of the disease. It is such as is found when the individual is exposed to such means as are known to produce spasm of involuntary muscular fibre. These are the application of cold to the surface, the administration of ergot, atropia, bromide of potassium, and lead. The condition of general paralytics is one, as a rule, of arterial contraction, but occasionally an hyperæmic condition is found. The mischief lies in a nutshell, which is vascular supersensitiveness. A patient whose pulse usually indicated vascular spasm, after drinking half-a-pint of asylum beer, exhibited a tracing such as is usually found in pyrexia, and his temperature rose from 97° to 98°. The opposite condition is often shown by attacks of cerebral syncope. In confirmation of the theory that the lesions seen after death are the results and not the cause of early organic changes, Dr. Thompson quotes the words of Dr. Long Fox, who says that 'variations in the normal blood-supply of the brain will, if long continued or frequently repeated, induce structural lesion that can be recognised after

death; each of them may be the starting-point of phenomena of a severe character, and if the duration of the attack be not protracted, will have no *post mortem* appearance' (*Pathological Anatomy of the Nervous Centres*). The cause of the arterial spasm, the blanching of the nervous system, is, according to Dr. Thompson, a heightened susceptibility on the part of the vaso-motor system to such influences as are likely to affect it. This heightened susceptibility takes the form of alternate overdilatation and overcontraction—of overstimulation followed by a reaction. But the reaction becomes a persistent condition. The paralysis of the sympathetic, causing dilatation, becomes an irritation, causing persistent contraction; this persistent contraction prevents the rapid flow of blood essential to the nutrition of the brain, and the phenomena known as brain-wasting are the result. He also points to the fact, as stated by Dr. Wilkie Burman in the third volume of the *West Riding Asylum Reports*, that the average weight of the heart is considerably greater in general paralysis, and in chronic and consecutive dementia, than in other forms of insanity, the supposition being that hypertrophy has been set up by the absence of dilatability of the vessels. For all this the Calabar bean is the best remedy at present known, but it must not be given during excitement, as has been done by some physicians.

[Dr. Milner Fothergill, in a paper on 'The Heart-Sounds in General Paralysis' (*West Riding Asylum Reports*, vol. iii.), speaks of the accentuated second sound of the heart in this disease, and attributes it to cerebral hyperæmia, a stage of hyperæmia with mental exaltation preceding one of atrophy, or brain-cirrhosis, where obliteration of the function of the brain co-exists. And in the fourth volume of the same reports he says, 'conditions of brain-anæmia are induced by the use of agents which depress and slow the heart's action, e.g., the Calabar bean, in states of cerebral hypervascularity, and for this purpose Dr. Crichton Browne has used the physostigma to control the wild outbreaks of general paralysis.'—*Rep.*]

G. FIELDING BLANDFORD, M.D.

DUBOUX ON RHEUMATISMAL INSANITY.—In a case of rheumatismal insanity reported in the *Bulletin Médical de la Suisse Romande* for Dec., 1874, the patient was suffering from acute articular rheumatism with endocarditis, and presented all the characteristics of rheumatismal madness; combination and alternations of various forms of mental alienation, mania, melancholia, dementia, with a marked predominance of notions of persecution and hallucinations of sight and hearing of a generally distressing character. For several days there was marked stammering, a symptom which has before been noted in some cases of this kind. M. Duboux brings into notice the commonness of melancholic mania in rheumatismal insanity; in the great majority of cases, coinciding with cardiac disease. On the other hand, it is interesting to note how amongst lunatics suffering from the persecution-delirium, generally with persistent hallucination, we find individuals labouring under heart-disease, especially amongst old men.

FOTHERGILL ON DIPSOMANIA IN WOMEN.—In the course of an almost exhaustive paper on cerebral anæmia in the *West Riding Lunatic Asylum Report* for 1874, Dr. Milner Fothergill states that he believes

that a chronic state of anæmia of the brain is the most common cause of dipsomania, especially in women. Alcohol, by increasing the force of the pulse and dilating the small arteries, removes for the time the feeling of weakness and utter wretchedness which is one of the most prominent and distressing symptoms in all cases of defective cerebral nutrition. Dr. Fothergill has treated successfully cases of dipsomania by measures having for their object the filling of the vessels of the brain. The means employed for this purpose must, of course, depend on the cause of the anæmia, whether it is part of a general state or due to cardiac weakness or to valvular disease, etc.: iron, digitalis, strychnia and belladonna are the most useful remedies, and, in bad cases, opium in frequently repeated small doses is of great service; it not only allays the restlessness and irritability which are generally present, but, by promoting dilatation of the small arteries of the brain, directly favours the nutrition of that organ.

J. W. LANGMORE, M.D.

OPHTHALMOLOGY AND OTOLOGY.

MAGNUS ON THE USE OF CALABAR BEAN IN IMPAIRMENT OF ACCOMMODATION.—Dr. Hugo Magnus (*Klinische Monatsblätter für Augenheilkunde*, August–September, 1874) remarks that the influence which is possessed by solutions of Calabar bean over the action of the ciliary muscles is universally recognised, and the extreme value of this influence in cases where the accommodation is suspended by paresis or paralysis of the ciliary muscle has been thoroughly well established. In this paper, it is the object of Dr. Magnus to show that the agent in question is powerful for good in many instances in which the action of the ciliary muscle is feeble and unequal to its task; in many cases, in fact, where we have to deal with symptoms of asthenopia. It has been shown, especially by Donders, that the asthenopia which is associated with hypermetropia may for a time be relieved by a single dose of Calabar solution; but it is the object of Dr. Magnus to show that by the employment of the solution for some days or even weeks the recurrence of asthenopia may be prevented altogether. In support of these views, the paper contains a brief account of ten cases which had been treated by instillation. The strength of the solution employed was one part of the extract to sixty parts of water, and five or ten drops were dropped in every night and morning, for a week at a time.

Case 1.—M. K., a girl aged ten, suffered from hypermetropia and amblyopia. Without the use of atropine, and with +60 glass, her vision = $\frac{16}{50}$. Asthenopia was present to such an extent that she was unable to work longer than an hour at a time. The treatment was commenced June 11, 1872, and at the end of three months she was able to do fine needlework without any difficulty, and without any return of her former trouble. How long this improvement in her condition remained, is not known.

Case 2.—S. A., aged twenty-two, a medical student, having vision with the right eye = $\frac{20}{20}$, with the left eye = $\frac{20}{40}$, was in the habit of wearing +40 glasses. The near point of the left eye for $1\frac{1}{2}$ Snellen's types was at seven inches, and he was unable

to accommodate with this eye for more than a minute. Distressing asthenopia occurred first in one eye and then in the other. This was soon relieved by the use of the drops, and the near point of the left eye was replaced at five inches. Before the cure was complete, there was a relapse of the asthenopia in this case.

Case 3.—H. G., aged fifteen, a school-girl, had hypermetropia and amblyopia. The vision of each eye was diminished one half; without atropine, +15 was the most useful glass; there was well-marked asthenopia. The treatment was commenced September 27, 1872, and at the end of a month the symptoms were so far relieved that she could work during the whole evening without trouble. At the termination of another month from the time the treatment was discontinued, there had been no relapse; but her acuteness of vision had not improved.

Case 4.—F. S., aged twenty-two, a clockmaker; his vision with either eye was = 1. Without atropine, +30 was his best glass, and this he was wearing. He had asthenopia. The improvement in this case was limited and not permanent, so that he was ordered to wear +24 glasses, as well as to persevere with the treatment.

Case 5.—L. O., aged thirteen, had hypermetropia and amblyopia; vision = $\frac{20}{30}$, with +30 glass. There was asthenopia, and this disappeared completely, so that the boy could do any kind of work. Six months later there came a slight relapse, but at the termination of the year the cure seemed to be complete and permanent.

Case 6.—P. K., a boy aged eleven, had vision with either eye = 1 with +50 glass. He had asthenopia, which was speedily relieved, so that he could work the whole day long. At the end of eighteen months there was a slight relapse, which yielded to similar treatment in a week.

Case 7.—A. M., a governess, aged eighteen; her vision was = 1 without atropine, and with +24 glass. She had asthenopia. This was soon relieved, but, as it recurred at the end of three months' time, the patient was ordered to wear convex glasses.

Case 8.—W. E., a young woman, aged twenty-two, had vision = 1 with +30 glass. There was extreme asthenopia. This yielded in some measure, but was never completely relieved.

Case 9.—S. R., aged eleven, had hypermetropia and amblyopia. Vision was = $\frac{15}{70}$, with extreme asthenopia. These symptoms were entirely relieved; but, as the boy did not continue his visits, the ultimate result of the treatment is unknown.

Case 10.—E. R., aged six, a girl, had hypermetropia and asthenopia, but her vision could not well be estimated. The hypermetropia was ascertained with the ophthalmoscope, and she was unable to read her school-books. The cure is reported to have been complete.

From the narrative of these ten cases, Dr. Magnus thinks he is able to prove that at least the ordinary symptoms of asthenopia may be relieved by the use of Calabar bean in solution, inasmuch as in Cases 1, 3, 5, 6, and 10, no glasses were necessary, and the simple instillation was sufficient to restore the functions of the ciliary muscle, and to replace the accommodation within its normal range, with no inconvenience to the patient whatsoever. Against this view, it may be said that in Cases 5 and 6 there was a recurrence of the asthenopia; but such relapses, he believes, may be prevented by perseverance with

the treatment. His observations, so far as they go, tend rather to show that an absolute and abiding cure is to be hoped for in patients of a certain age only; for instance, in Cases 2, 4, 7, and 8, the age was greater than fifteen years, and in all of these the improvement was limited, and the use of the drops had to be supplemented by the employment of convex glasses.

Dr. Magnus thinks that his plan of treatment is well suited to all cases of asthenopia in children; and he believes it will be found of great value in all cases which display a tendency to strabismus, inasmuch as, by increasing the amount of accommodation without at the same time straining the convergence, the conditions which tend to the development of a squint are not present in so high a degree.

The continued employment of the curative agent appears to have been attended with no difficulties. The conjunctiva in no way resented the frequent application of the drops, and the patients never complained of pain, the little girl, Case 10, excepted; but her complaints can hardly be said to afford any true criterion, and the author thinks that he can assert this much, if no more, that his observations go a great way to show that in Calabar bean we possess a curative agent whose influence is greater and wider than has been supposed. BOWATER J. VERNON.

MISCELLANY.

MDLLE. LEHMUS, of Furth, Bavaria, has just received from the Faculty of Medicine of the Zurich University the diploma of doctor in medicine, surgery, and obstetrics.

FACT *versus* FICTION.—The authorities of the Nottingham Free Library have written to the Vice-Chancellor of Cambridge to state that, since the institution of local examinations, the issue of works of fiction has declined and given place to the reading of scientific books.

A ROYAL SAVANT.—Don Pedro, Emperor of Brazil, has just been named corresponding member of the French Academy of Sciences, in the section of navigation and geography. He is the only sovereign who has been enrolled amongst the active members of this illustrious scientific body since its foundation in 1866.

IT will be remembered that M. Pajot, who had the intention of giving up his chair of obstetrics at the École de Médecine, relinquished his purpose on the earnest representations of the students. He commenced his sessional course of lectures on the 16th inst., when the students took occasion to give him an ovation of the most enthusiastic and gratifying character.

THE ACTION OF NICOTINE.—In the report of the West Riding Lunatic Asylum, Dr. Benham has a paper on this subject. He administered nicotine to man and the lower animals, finding that it killed the latter, not by paralysing the heart, but by stopping the respiration. Indeed, he says, it quickens and strengthens the heart's action, and recommends its use for that purpose. He found that nicotine contracted the pupils, but its other effects on man were most variable.

THE Ateneo Propagador de las Ciencias Naturales offers a prize of 500 pesetas (about twenty guineas) for the best original memoir on the mineralogy, botany, or zoology of Spain. Any person, whether a member of the society or not, can compete for this prize. Memoirs must be sent in to the secretary of the society before September 30, 1875. A printed paper with further particulars may be procured from the secretary, whose address is Calle Ancha de San Bernardo, 15, Madrid.

SIGNOR PERUZZI, the Syndic of Florence, has given orders that 800 out of the 1,000 dogs annually found straying in that city, which have for some years past been placed at the disposal of Professor Schiff, shall be killed by the police. They are to be asphyxiated instantaneously in a cell constructed for the purpose, and filled with carbonic acid gas, which is being prepared in the precincts of the public slaughter-house.

THE ORIGIN OF NERVE-FORCE.—In a discussion between Herbert Spencer and Professor Clerk Maxwell, on this subject, given in the *Quarterly Journal of Science*, January, 1875, the former maintains that when the nerve impulse is expended, the nerves fall in temperature and are reinforced by instantly absorbing heat from the adjacent tissues. To this Professor Maxwell replies, that 'those who believe in thermo-dynamics cannot admit that any purely material system can convert heat into work when the system and its whole environment are, at the commencement of the operation, at the same temperature. Heat can do work only when it passes from a hotter body to a colder.'

THE MARRIAGE OF COUSINS.—The March number of the *Deaf and Dumb Magazine* contains an article on the 'Marriage of Cousins,' by the Rev. S. Smith, the editor, which is nearly identical with the remarks of that gentleman published in the *Times* of the 19th ultimo. In his paper Mr. Smith asserts—and adduces many painful proofs of his assertion—that such marriages are the fertile source of congenital deaf-mutism and other physical defects and disqualifications. He insists upon the necessity of such evil consequences being universally made known, in order that their entailment may be avoided. This subject is one which well deserves the serious attention of the philanthropist as well as the social and political economist, and, indeed, of all classes of the community.

THE PREVAILING HOUR OF DEATH.—Dr. Lawson has recently published some curious observations regarding the time of the day when the greatest and least number of deaths occur. He finds, from the study of the statistics of several hospitals, asylums, and other institutions, that deaths from chronic diseases are most numerous between the hours of eight and ten in the morning, and fewest between like hours in the evening. Acute deaths from continued fevers and pneumonia take place in the greatest ratio in the early morning, when the powers of life are at their lowest, or in the afternoon, when acute disease is most active. The occurrence of these definite daily variations in the hourly death-rate is shown, in the case of chronic diseases, to be dependent on recurring variations in the energies of organic life; and in the case of acute diseases, the cause is ascribed either to the existence of a well-marked daily extreme of bodily depression, or a daily maximum of intensity of acute disease.

THE DAWN OF LIFE.—Professor Williamson, in a lecture on the 'Dawn of Life,' delivered at Glasgow on the 2nd inst., referred to the experiments of Dr. Bastian, and remarked that one positive experiment showing that animal life did not result after the application of heat, and the careful exclusion of the atmosphere, was of more value than a hundred experiments giving an opposite result. He mentioned an interesting fact derived from the recent experiments of two Liverpool gentlemen who had sedulously watched by a powerful microscope the habits of the infusoria. They subjected the water in which they were contained to 250° of heat, and found that, while the mature animalcules were destroyed, the germs were not, but a heat of 300° destroyed the germs also. Professor Williamson believed that if these experiments were verified, the question of spontaneous generation might be considered to be practically settled. The deepest reaches of the microscope had shown that life was produced from life—that this one universal law prevailed in the organic world just as the farthest reaches of the telescope had shown that gravitation prevailed in the remotest systems in space.

CINCHONA OR CHINCHONA.—Mr. C. R. Markham, in a lately-published *Memoir of the Lady Ana de Osoria, Countess of Chinchon and Vice-Queen of Peru*, wishes to prove that the name cinchona, applied to Peruvian bark, should be altered to chinchona. The knowledge of the efficacy of Peruvian bark was undoubtedly brought to Europe in the year 1640 by the Countess of Chinchon, on her return to Spain with her husband at the expiration of his term of office as Viceroy of Peru. This lady, during her residence there, was attacked by tertian fever, and cured by the use of Peruvian bark. On the return of the count and countess to the castle of Chinchon, the countess, who had brought with her a supply of the precious bark which had effected such a wonderful cure upon herself 'administered Peruvian bark to the sufferers from tertian agues on her lord's estates in the fertile but unhealthy *vegas* of the Tagus, the Jarama, and the Tajuña. She thus spread blessings around her, and her good deeds are even now remembered by the people of Chinchon and Colmenar in local traditions' (p. 45 of the memoir). Though from time to time during the succeeding hundred years powders of the Peruvian bark were imported into Europe, no scientific account of the tree was published until 1740, in which year De la Condamine published a description and figure in the *Memoirs of the Academy of Paris* for 1738, under the generic name of *Quinquina*. This communication contained also an account of the history of the drug, wherein the name of the Countess of Chinchon was duly mentioned and properly spelt, and on the information obtained from it and quoted in acknowledgment, Linnæus, in the second edition of his *Genera Plantarum*, published at Leyden in the year 1742, founded his genus *Cinchona* in honour of the Countess of Chinchon. The word cinchona, however, has now become settled by the usage of upwards of a hundred and thirty years, and sufficiently recalls the name of the enlightened and benevolent lady to whom Europe owes the introduction of this most useful therapeutic agent.

SCHOOL IMPROVEMENTS.—In all cases where class-rooms are lighted by gas during day-time, the Inspectors of Schools recommend the principals and the committees to have greater regard for the health and comfort of the pupils, by availing themselves of that useful modern invention, the Daylight Reflectors, of which for many years Mr. Chappuis has been the successful patentee and manufacturer, at 69 Fleet Street, London. Not only will the rooms be more healthy, but a considerable saving will be effected. The cost of the Reflectors is moderate, and their durability will extend over several years.—[ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MARCH 31, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

WEIR MITCHELL AND CHARCOT ON POST-PARALYTIC CHOREA.

It is very well known that choreal movements, in some cases of hemichorea, are replaced by hemiplegia; but it is not so well known that choreoid movements sometimes follow hemiplegia. There are to be found, in what we may call the hemiplegic region, all varieties of mobile disorders. There are curious mixtures of palsy and spasm, and the limb which the patient cannot use may often twist about to his great discomfort. For these over-movements thus localised, the reporter has suggested the general name of Hemikineses. In close relationship with hemiplegia is hemispasm—convulsion of one side. Not only does hemiplegia (temporary) follow this variety of hemikinesis, but not unfrequently convulsion attacks a patient partially hemiplegic, and begins in and affects first and most the parts paralysed. In adult patients, hemiplegic from infancy, there are frequently over-movements of the paralysed arm, and, in less degree, of the leg; but the reporter has not seen movements like ordinary chorea in such persons. The movements lack the punctuation of chorea; they are not a succession of different movements, but a gliding of movements into one another. In some of these cases the patient is subject to convulsions as well, which, however, rarely begin deliberately in the side of the body most affected by the palsy and the over movement. In some cases of tumour of the brain, as Todd and Tuckwell have pointed out, chorea-like movements result. Again, in some cases of 'coarse disease,' syphilitic, for example, of the surface of a cerebral hemisphere which has led to epileptic hemiplegia, there are, during recovery from that hemiplegia, various kinds of slight movements; the arm will often jerk fitfully, the thumb and index finger will move much as they do in paralysis agitans. In some cases the limb is still when the patient is not trying to move it; and yet, when he tries, there is tremor indistinguishable from that of disseminated sclerosis.

One advantage likely to result from the comparative study of the different kinds of movements of the hemiplegic region in relation to loss of movement in that region (hemiplegic) is, that the needful empirical study of cases will be controlled by scientific method.

In an exceedingly valuable contribution to the *American Journal of the Medical Sciences*, October, 1874, Dr. Weir Mitchell calls attention to a disorder which he names postparalytic chorea. The paper is a commentary on three chief propositions: 1. That, in adults who have had hemiplegia and have recovered power, there is often found to be a choreal disorder in the members affected by the paralysis; 2. That, the

younger the patient when paralysed, the more probable is the occurrence of choreal development; 3. That probably some of the congenital choreoid disturbances are in some way related to intra-uterine palsies.

Postparalytic chorea is rare; it is not found in cases of hemiplegia where much palsy remains; it does not come on suddenly, but grows slowly, increasing as the paralytic state fades out. It does not occur in connection with rigidity; it may exist with any degree of regained power, from the least up to the most complete; it occurs on either side; it is worse in the region of complicated motions.

The occurrence of postparalytic chorea is so much more frequent after hemiplegia in the young, that very few cases of hemiplegia in young children fail to leave behind them more or less choreal inco-ordination. It is probable that choreal disturbance does not follow spinal infantile paralysis.

Several cases are quoted by Dr. Mitchell, one of which is completed by a necropsy. In that instance there were two attacks of hemiplegia, the first on the left, and another, more than a year after, on the right. The latter was followed by choreoid movements, which, it is implied, were in both legs and one hand, though it is not explicitly stated. At the necropsy some months after the latter attack, a spot of pigmented softening, probably old, was found in the right crus cerebri, a second in the left corpus striatum, and a third, of the size of a pigeon's egg, on the under surface of the middle lobe on the left side.

Dr. Mitchell also speaks of other postparalytic disorders of movement, which cannot be called choreal. One patient, after right hemiplegia, incessantly rubbed the right leg with the right hand, so as even to wear out his pantaloons.

In one of his recent masterly lectures (*Le Progrès Médical*), Charcot relates three cases of the post-hemiplegic chorea of Dr. Weir Mitchell. The first patient, M. R., aged fifty-one, had an apoplectic attack ten years ago, with loss of consciousness and vomiting; this was followed by complete right hemiplegia and ataxy of articulation. At the end of six months she was able to get about, and, as power of movement in the right leg returned, the right arm became affected with choreiform tremor, which has remained ever since. At the present time she has general right hemianæsthesia, exactly like that of hysteria. General sensibility is so diminished, that a large pin can be thrust deeply into the face, trunk, and limbs on the right side, without causing any sign of pain. Acuteness of vision is diminished in the right eye; smell is altogether lost on that side; a watch is heard dimly with the right ear; taste is abolished on the right side of the tongue. There are no motor troubles in the face. The right arm and leg are neither atrophied, contracted, nor in any way deformed. While they are at rest, there is scarcely any motor disorder; but on voluntary movement they present a choreiform agitation like that of insular sclerosis, and somewhat similar to the tremor which occurs in ordinary hemiplegia when the lateral columns of the cord have degenerated and there is not much contraction of the limbs. The movements have no resemblance to those of locomotor ataxy, nor does the fact of the patient's keeping the limbs in view exert any influence over them. On the other hand, they differ from the tremor of sclerosis and that of hemiplegia in existing in the absence of voluntary movement. He applies, therefore, the name chorea to these movements, although it is intended thereby to indicate a similarity only,

and by no means a nosographical identity with ordinary chorea.

Posthemiplegic hemichorea occurs not only after cerebral hæmorrhage and softening, as seen in adults, but also after those changes which occur in infants, and are known as partial atrophy of brain (Cotard). There is, as a rule, in these cases, incurable hemiplegia with contraction; but in rare instances the hemiplegia is from the first supplanted by a hemichorea, which lasts for the rest of the patient's life. Charcot reports two such cases, in which, after hemiplegia in infancy, hemichorea without anæsthesia persists to the present time, when the patients are eighteen and twenty-nine years old respectively.

The condition is so uncommon that Charcot has seen only five or six cases in the last twelve years.

Charcot does not at present offer a definite explanation, but he thinks it probable that the substitution of choreiform movement for flaccidity or contraction depends on a difference in the seat of the cerebral lesion. He founds his opinion chiefly on the fact that the hemichorea is usually accompanied by hemianæsthesia. He considers it established that hemianæsthesia, extending to the special senses, is due to a lesion of (1) The posterior extremity of the optic thalamus; (2) The most posterior part of the caudate nucleus; it is expressly noted that the anterior two-thirds or three-quarters of these nuclei are wholly unaffected; (3) The most posterior part of the base of the corona radiata. He has found ochrey cicatrices in this situation in three cases of unilateral hemianæsthesia; but he admits on the other hand that he has seen very many cases in which these nuclei were injured in various parts without there being the least trace of choreiform movements. He does not, therefore, suppose that these organs are necessarily involved, but rather, although he puts it forward as a mere hypothesis, that there are, among the thin fibres of the corona which convey sensory impressions, fasciculi endowed with special motor properties, the alteration of which determines hemichorea.

In connection with posthemiplegic hemichorea, Charcot describes an inverse affection, which he calls prehemiplegic hemichorea, in which choreiform movements, coming on suddenly after an apoplectic seizure, shortly give place to more or less complete hemiplegia. Hemichorea of this nature is always accompanied by hemianæsthesia. Charcot has seen but three cases of this kind, and in only one has he had a necropsy. In that case there was a blood-clot of the size of a small nut, which distended the posterior part of the optic thalamus.

Hemichorea, accompanied or not by hemianæsthesia, may be produced slowly and progressively without being necessarily preceded or followed by hemiplegia, in consequence of the growth of certain neoplasms in the substance of the hemisphere. In the case of a woman still living, aged sixty, there have been vague pains in the right arm for fifteen years. Six years ago she had epileptiform attacks, and about the same time a choreiform movement began in the right arm. The movement is permanent, increased by voluntary exertion, and resembles chorea more than either paralysis agitans or senile tremor. During the last year this patient has had total right hemianæsthesia, with involvement of the special senses. J. HUGHLINGS JACKSON, M.D.

DWIGHT ON COLOURING AGENTS IN HISTOLOGY.

Dr. Thomas Dwight, jun. (*Boston Medical Journal*) observes that, were the object of colouring a microscopical preparation merely to render the different elements more distinct, or even were it to enable us to form some judgment as to the degree of vitality of certain parts of cells and fibres, we should not need to chronicle the introduction of new agents: but, as the real desideratum is something that by its action will enable us to determine the nature of such bodies as it does or does not colour, we welcome every addition to our slight knowledge in this respect.

Of all forms of tissue the connective is the most perplexing, owing to its universal distribution, and to its intimate relations with other tissues, from which it frequently can hardly be distinguished, if at all.

Ranvier (*Archives de Physiologie*, no. 6, 1874) asserts that he has found a colouring matter called purpurine, which will be of great use in this respect. It is particularly applicable to the study of the central nervous system, from its property of colouring the nuclei of connective tissue cells and of leaving nervous elements unstained. To obtain this effect, the cord should be hardened in bichromate of ammonia. The nuclei of cartilage-cells, corneal corpuscles, and fixed cells of connective tissue in general are admirably shown. The substance is an extract of madder, and the fluid is made by adding it to a boiling solution of one part of alum and two hundred of water until some of the extract remains undissolved. The fluid is filtered while still hot into enough alcohol to form one quarter of the mixture. Only a small amount should be prepared at a time, as precipitation occurs in about a month, after which the staining properties are less active. The colour is a fine orange-red. From twenty-four to forty-eight hours are required for staining; most preparations are then mounted in glycerine, but sections of the cord are freed from water and rendered transparent *secundum artem*, and mounted in a solution of Canada balsam in chloroform.

Alferow (*Archives de Physiologie*, nos. 4 and 5, 1874) advocates the use of the lactate of silver instead of the nitrate. He recommends a solution of one part in eight hundred of distilled water, with the addition of a few drops of a concentrated solution of lactic acid. The presence of the free acid renders precipitation less easy, and the only formations that occur are the chloride and albuminate of silver. The formation of several disturbing precipitates is thus avoided. Alferow asserts that the pictures are much clearer than those obtained by the nitrate, and that the lactate, if applied to the mesentery of the living frog, interferes less with the circulation. We may mention incidentally that this author denies the existence of stomata in blood-vessels and serous membranes, and states that solid particles traverse epithelial layers between the cells, which move to give them passage by some mechanism not yet understood.

Gerlach, in an excellent monograph on the relations of nerve and voluntary muscular fibre in vertebrates, gives directions for the use of silver, osmic acid, and gold. It is to be remembered that his directions apply only to this special branch of study. In speaking of silver he dwells on the fact (which is more or less true of all colouring matters) that its action is

very different on living and on dead tissues. With muscles this is particularly important, as the acid reaction due to contraction interferes with the effect of the silver. He uses silver as follows: a little muscle is picked to pieces in a half of one per cent. solution of salt in water, and allowed to remain in this fluid eight or ten minutes, after which it is washed in distilled water, and transferred to the tenth of one per cent. solution of the nitrate of silver, to remain till it assumes a dull white colour, which usually appears in about half a minute. The muscle is then again washed, and exposed in a moist chamber to direct sunlight, if possible, for five or ten minutes, or to diffused light for four times as long. It is then treated for three or four minutes with a mixture of one part of hydrochloric acid and one thousand of water. Silver, though having for the most part a purely superficial action, shows in the substance of the muscular fibre itself a series of white markings, which Gerlach is inclined to consider lymph-spaces.

Osmic acid has a peculiar affinity for the white substance of the nerve-fibre; no coagulation takes place, but the whole fibre appears as a black band. For tracing the general distribution of nerve-fibres, this agent is very serviceable. There are several methods of using it, but the following is the simplest and the most generally applicable. Put the specimen for from four to eight minutes in a half of one per cent. solution of the acid, then wash it and mount it in a saturated solution of acetate of potash. Glycerine is not to be recommended.

For the finer nervous filaments, gold is superior to anything else. Gerlach, in place of the simple salt, uses the chloride of gold and potassium dissolved in ten thousand parts of water, with one part of chemically pure hydrochloric acid added to the solution. It is important to know that the action on muscles is modified by the length of time after death, and by the state of the muscles before death. The best results are obtained with muscle that is not perfectly fresh, but which is used before the development of cadaveric rigidity. For the frog the best time is from six to nine hours after death; in warm-blooded animals the examination must be made sooner. It seems also desirable that just before death the muscle should have been in a state of tetanic contraction. In the frog this is brought about by killing the animal by repeated blows on the head. Beale's more humane method of wrapping the frog tightly in a towel and dashing it to the ground would doubtless be equally advantageous. The extremity from which the muscle is to be taken should be separated at once. The specimen is kept ten or twelve hours in the gold solution protected from the light. It is then washed in slightly acidulated water and mounted in glycerine, to which a little hydrochloric acid has been added.

Schiefferdecker (*Archiv für Mikroskopische Anatomie*, Band x. Heft 4, 1874) describes some very beautiful sections that he had made with the cord of a dog and stained with chloride of gold or chloride of palladium. The former of these is particularly good for showing the net-work of minute fibres, while the latter shows the course of the larger ones very finely. The fresh cord, stripped of its membranes, was hardened by being kept for a month in Müller's fluid, and then for twenty-four hours in alcohol. The sections were washed for a day or two in distilled water. The solution of palladium was of the strength of one to ten thousand; that of gold,

sometimes the same, sometimes twice as strong. The specimen was kept in the palladium till it became of a grey colour, which occurred in from three to five hours; it was then washed in distilled water. Those specimens treated with gold were kept in till they became of a light violet, which took place in from one to three hours; they were then kept for a day in acidulated water. The specimens of both kinds were finally mounted in Canada balsam, after the regular course of alcohol and oil of cloves.

Ranvier (*Archives de Physiologie*, no. 6, 1874) recommends weak alcohol as a substitute for chromic acid, Müller's fluid, and other hardening agents. He adds twice its volume of water to alcohol of 36° of Cartier's scale, that is, of about ninety per cent. This fluid renders the cells rather hard, the nuclei very plain, and at the same time dissolves the intercellular substance; hence it is very useful in the study of individual elements. It further has the merit of not interfering with the action of colouring agents.

JOHNSTON'S REPORT OF THE ROTUNDA LYING-IN HOSPITAL.

The following is an abstract of Dr. George Johnston's sixth clinical report of the Rotunda Lying-in Hospital for the year ending 1874.*

The author's only object is to give an accurate and faithful detail of the occurrences taking place in a large maternity, in order to arrive at a fair conclusion whether such an institution is as safe, if not safer, than a private dwelling. On comparing last-year's mortality with former years, it is found to be considerably less, the number confined being greater.

		Deliveries.	Deaths from all Causes.	
In 1869	out of	1,159	there were	25
" 1870	"	1,087	"	27
" 1871	"	1,161	"	33
" 1872	"	1,193	"	20
" 1873	"	1,191	"	32
" 1874	"	1,236	"	15

This great diminution is the more remarkable as zymotic diseases of all kinds were very prevalent outside the hospital; and, besides this, many patients were admitted labouring under acute complaints or became affected shortly after admission. Sixty were suffering from great mental distress (forty-seven seduced, seven deserted by husbands, three ill-treated, three lost their husbands shortly after coming in); twenty were extremely delicate; forty-four had acute bronchitis; three jaundice; one gastritis; five convulsions; two epilepsy; five mania, one terminating in apoplexy; two phlegmasia; one phlebitis; thirteen peritonitis; one pyæmia; four syphilis; one had a lacerated wound over the sacrum extending to the right labium; two had fever; one typhus; one typhoid; two diarrhoea; two erysipelas; two rubeola; fifteen scarlatina; five rheumatism.

The low death-rate is viewed as mainly owing to strict cleanliness, a constant current of air permeating the wards and corridors, and preventing labour from becoming protracted by early interference, besides saving the lives of many children thereby, and obviating the dangers arising from exhaustion and long-continued pressure on the soft parts.

* Read before the Dublin Obstetrical Society, January 9, 1875.

Of the 1,236 labours, 967 were purely natural ; in 40, labour continued beyond twenty-four hours.

The chief part of these cases were sent in by practitioners and midwives who had failed to deliver. In forty-five instances, the ovum was expelled before the sixth month. There were twenty-three cases of twin-births ; three presentations of the upper extremities, forty-five of the lower. The forceps were used with 138 patients, the perforator never ; version fourteen times. Seven cases of accidental hæmorrhage, and six of placenta prævia were admitted. There were twenty-five cases of *post partum* hæmorrhage (trivial) seven of retained placenta, thirteen of prolapse of funis. Chloroform was administered 104 times. There were fifteen deaths, or one in 82½ ; nine from diseases of a zymotic type, viz., three from scarlatina, three from peritonitis, one from pyæmia, one from typhus, and one from typhoid fever.

There are fourteen most carefully drawn up and instructive tables. Table 1 contains a monthly abstract of deliveries, casualties, and complications, modes of delivery in difficult cases, preternatural presentations, abortions, twins and unnatural labours. Table 2 shows the deaths, with date of delivery, of death, ward, bed, age, number of pregnancy, causes, and observations. In the case of death from complete placenta prævia, Barnes's dilator was introduced, and, when the os was sufficiently dilated, version was performed. The patient died an hour and a half after delivery. The necropsy showed laceration of the vagina and cervix. In the instance of death from sloughing, the patient was delicate on admission through early rupture of the membranes. Labour was retarded ; the forceps was applied when the os was only two-fifths dilated ; sloughing of the vagina and peritonitis supervened. There were only three cases of peritonitis. The forceps was applied when the os was two-fifths dilated, for early rupture of the membranes and separation of symphysis pubis with purulent deposit. Of the patients who died, twelve were primiparæ, four of whom were seduced ; one fretted very much, another was remarkably silent. Of the three multiparæ, one died of placenta prævia (eleventh pregnancy), one of typhoid, and the other of typhus.

Of the forty cases of labour exceeding twenty-four hours, thirty-four were primiparæ and six pluriparæ. All of the primiparous patients were delivered by forceps except one. In the multiparous cases the forceps was used three times, version in one case, and twice the natural efforts sufficed. Two mothers died (primiparæ) ; one was twenty-six hours in labour, the other thirty. Of the children, five of primiparæ and three of pluriparæ died. Out of forty-five cases of abortion, nine were in primiparæ, of which five were at the sixth week (one in a primipara), seven at the eighth week (one a primipara), eleven at the twelfth week (one a primipara), four at the sixteenth (one a primipara, from a fall), one at the fifth month from a fall, seventeen in the sixth month (five being primiparæ). In the primiparæ, all the children were putrid. Of premature births there were fifty-one instances ; thirty-one in the seventh month (eight primiparæ), twenty in the eighth month (ten primiparæ). It is rather remarkable that during the first five months abortions were very rare in primiparæ ; after that time the proportion gradually decreased, until by the eighth month they were equal. Out of the twenty-four cases of twins, eight were in primiparæ (one of whom died), sixteen in pluriparæ.

The forceps was applied in 138 instances, viz., in 105 primiparæ, in which latter number only three children were born dead, 102 being living ; of these three born dead two were delivered before the os was fully dilated, and were large children, over seven and a half pounds. The waters ruptured many hours previously, two of the mothers had contraction of the conjugate diameter. Five deaths occurred amongst the primiparous mothers ; one was a case of twins, in which death occurred from apoplexy ; one died from scarlatina, one from bronchitis, one of sloughing of vagina with peritonitis, and one from peritonitis.

Of the thirty-three pluriparæ, seven of the infants were still-born and four died shortly afterwards. Of the still-born children, one was a breech case, two had prolapse of the funis, one was a case of placenta prævia ; one where the forceps was used with the os two-fifths dilated, and the child was very large ; the waters had escaped six days. One case, where the waters had escaped twenty hours, the os was four-fifths dilated, the head was above the brim twenty-five hours, and one was a hydrocephalic child retained in the cavity of the pelvis.

The forceps was applied forty-two times before the os was fully dilated, thirty-four times in primiparæ, eight in pluriparæ. As the plan is a deviation from usual routine practice, a carefully prepared table is given (no. 9.) showing the exact conditions under which Dr. Johnston deemed the operation advisable. Deducting two cases, a married and a single woman, who were only eight and six hours respectively in labour, the mean was twenty-five hours. Thirty-four children were born living, and four died, two of each state, primiparæ and multiparæ. The cause of interference was in thirty-four cases, viz., twenty-nine primiparæ and five multiparæ, one for placenta prævia, and seven not given.

The author divides the os into five divisions ; assuming that a dilatation of four inches is the full normal extent to which the os can be expanded. A lithographed plate is given, showing on a full scale the relative proportion between the forceps and the degrees of dilatation. The width of the forceps-blade is reckoned at 18th of an inch. The forceps was applied in twenty-four instances, nineteen primiparæ and five pluriparæ, with an expansion of the os of only two-fifths ; twelve times (eleven primiparæ and one pluripara), with a dilatation of three fifths, and lastly in four primiparæ, with a dilatation of one-fifth. The state of the os in these married women is not given. The head was above the brim in six primiparæ and five multiparæ ; in the brim in fifteen primiparæ and two pluriparæ, and the cavity in thirteen primiparæ and one pluripara. One primipara died of pyæmia ; the os was two-fifths dilated when the forceps was applied ; the head was above the brim, the waters ruptured early, and she was twenty hours in labour. One pluripara was thirty hours in labour ; waters ruptured early ; the os was two-fifths dilated ; the head was in the brim ; she died of peritonitis.

The causes of interference were ; 1. (the most frequent) early rupture of the membranes and escape of the waters before the os was dilated, and the head pressing injuriously on the maternal soft parts ; of these there were thirty-four cases (twenty-nine primiparæ and five pluriparæ ; 2. Although the membranes were entire, the head came down and pressed upon the soft parts without the usual intervening bag of waters ; of this there were six instances—

four in primiparæ and two in pluriparæ; 3. prolapse of the funis; and 4. placenta prævia.

Craniotomy was not once performed. Version was performed fourteen times, all in primiparæ; in four for presentations of the upper extremities, of which two were for second of twins, and two for single cases; four times for placenta prævia, three complete (one of the mothers died from laceration of the cervix and vagina), and one partial; twice for accidental hæmorrhage; three for the second of twins (head presentations); once for prolapse of the funis. Chloroform was given ten times; all the mothers recovered with the above exception. In seven cases of accidental hæmorrhage, one was a primipara, six pluriparæ. One mother died of typhoid fever. Placenta prævia happened five times, all pluriparæ; all the children were born living, two died. One mother died from hæmorrhage.

Post partum hæmorrhage.—The author divides it into three classes: 1. Slight trickling, where external pressure is alone sufficient to arrest it, together with cold applications, and the pulse unaffected; 2. Where the injection of cold water into the uterus or vagina is necessary, with use of ergot, wine, perhaps an opiate, the pulse being little affected; 3. Great draining, with faintings, the pulse affected; requiring strong remedies. In Table 10, the cases are divided under these separate heads. There were 27 cases; 23 were confined naturally, 4 by forceps; 9 were primiparæ, 18 pluriparæ. All the children were born living, and the sexes were equal. Chloroform was given only 3 times; the duration of the second stage never exceeded five hours, and in 21 cases not two hours. The third stage was never over 22 minutes. In 14 cases the hæmorrhage yielded to cold and ergot; 10 required cold injections, 3 per-chloride of iron. All recovered. The forceps was used twice before the os was fully dilated. Out of these cases 6 of the mothers left the hospital on the sixth day; 5 on the seventh; 8 on the eighth; 5 on the ninth; 1 on the tenth; 1 on the eleventh (a case of jaundice); 1 on the nineteenth day (an epileptic). The character of the cases was not serious.

As the question of the shortness of the second stage conducing to *post partum hæmorrhage* is still *sub judice*, Dr. Johnston has given a most carefully drawn up table (no. 11) showing the number of cases where the second stage did not exceed one hour for each month, with the number of cases of *post partum hæmorrhage* which occurred in them. There were 684 cases with 14 instances of *post partum hæmorrhage*; 7 of the first degree, 5 of the second degree, and 2 of the third degree. The writer sums up by saying that in the great majority of cases *post partum hæmorrhage* depends upon want of proper manipulation, *i.e.*, keeping a constant steady pressure over the uterus, from the moment the child's head is being expelled from the vulva, until the expulsion of the placenta and the application of the binder, which should be so arranged as to secure the uterus from relaxing. By observing strictly this practice not only is the complication avoided, but the completion of the third stage in a very short space of time is favoured, which is shown in a separate table (no. 12).

The placenta was expelled with the fœtus in fourteen instances; in 542 within 5 minutes (with 11 cases of hæmorrhage); within 10 minutes in 399 women (with hæmorrhage 10 times); within 15 minutes in 131 (with 5 cases of hæmorrhage); and in 55 within 20 minutes (with no flooding); in 17 within 25

minutes (with one case of flooding); in 15 at 30 minutes (without hæmorrhage); in 9 at 35 minutes, with same result, of whom 2 had morbid adhesions and 6 inertia; in 5 at 40 minutes (2 had irregular contractions, and 3 inertia); 2 at 50 minutes, in one at 60 minutes, and in one at 65 minutes, with like result. The last 3 cases were attended by the pupil in charge. The placenta was retained 11 times; in two from morbid adhesions; two from irregular contractions; in seven from inertia; two primiparæ and five pluriparæ. In all of these latter cases, it was squeezed out, within forty-five minutes.

Prolapse of the funis happened 12 times; 4 times in primiparæ, 8 in pluriparæ. Of the primiparæ one child was born putrid and dead, and two living. Of the pluriparæ four children were still-born, two of whom were putrid, and two died shortly after birth. Version was performed twice; the children were saved. The forceps was used 6 times—2 children were preserved. There were two footlings, one of which was saved; and two were left to natural efforts, the cord in each case being pulseless on admission.

Of scarlatina 15 cases were admitted, 14 of which were in primiparæ. The rash appeared in 8 on the second day, and in 3 on the third day; 6 were not sent out of hospital, 3 of whom died. The disease never spread in the wards. There was one case of typhus and one of typhoid. There were 9 cases of peritonitis, exclusive of those who died; 5 were in primiparæ, 4 in pluriparæ. One patient had phlebitis, and recovered.

Table 13 gives the exact number of patients delivered; the number of the ward, with the deaths as they occurred.

There were 380 primiparous cases, of whom 12 died, 7 from zymotic disease; 858 were pluriparæ, of whom 3 died, 2 from zymotic diseases.

Table 14 gives the number of deaths from zymotic diseases in the several poor-law districts during the twelve months, and the number of patients admitted from each district and delivered in the hospital, together with the number of deaths that took place amongst them of a zymotic type. This is done in order to show 'a large maternity is not the centre of zymotic diseases, nor does it engender epidemics.' Out of 758 deliveries of persons coming from the 3 northern districts there were 7 deaths, whilst in the districts themselves there were 757 deaths; and of the 478 delivered, coming from the southern side, there were 2 deaths, against 1,233 occurring outside in the district.

In the discussion which followed the reading of the paper, the president, Dr. Athill, called attention to the remarkable application of the forceps, before the os was fully dilated. Whilst believing that such practice was safe in the hands of so skilled an operator as Dr. Johnston, he thought for the unskilled and inexperienced practitioner it would be dangerous to a degree and absolutely unsafe. He considered a mortality of $\frac{1}{3}$ per cent. from puerperal causes was as favourable a report as could be given by any practitioner in the kingdom.

Dr. Cronyn bore testimony to the ease with which Dr. Johnston applied the forceps, and delivered when the os was no larger than a halfpenny.

Dr. Henry Kennedy believed that when a patient, after admission into the hospital, exhibited signs of sickness totally independent of what might be expected to arise in connection with pregnancy, the probability was that the seeds of disease were im-

planted in her before she entered the hospital, the act of delivery being sufficient to bring to life and to develop the disease. Dr. Kidd inquired whether it was ever found impossible to deliver when the forceps was applied before the os was fully dilated. Dr. Johnston replied in the negative, and related a case he had succeeded in delivering, where craniotomy had been previously performed. He strongly advocated the double curved forceps as the more useful instrument.

Dr. M'Clintock thought it must be now a received fact, from Dr. Johnston's cases, that the forceps can be applied with safety both to mother and child before the os is fully dilated, but knowing that the first stage of labour can be prolonged to a great length with impunity to mother and child, he considered it would be a most hazardous practice to apply the forceps when the head was high up in the brim, simply because the labour was tedious through a rigid os; at the same time, in case of an emergency, such as prolapse of funis or convulsions endangering life of mother or child, it would be justifiable, and, in future, a source of great comfort to know that they could be employed in this stage with impunity.

Dr. Johnston, in conclusion, took exception to Dr. M'Clintock's opinion that the prolongation of the first stage could be allowed to proceed with little or no danger to the patient, and related a case which deeply impressed him to the contrary, where a woman had been allowed to remain in the first stage for a considerable time, dying subsequently, and the necropsy revealing a complete separation of the cervix from the body of the uterus. He has never had occasion to regret his bold step. Respecting Dr. Kidd's observation of the unyielding and rigid os requiring an enormous and dangerous amount of force to dilate it, he found with gradual traction the os soon yielded and expanded.

W. C. GRIGG, M.D.

ANATOMY AND PHYSIOLOGY.

MALASSEZ AND PICARD ON MODIFICATIONS OF THE BLOOD IN ITS PASSAGE THROUGH THE SPLEEN. Researches on this subject hitherto have yielded contradictory results. Some observers (Beclard, Lehmann, Gray), have found the proportion of corpuscles smaller, after passage of blood through the spleen, while Franke has asserted it to be larger.

The authors thought (*Comptes Rendus*, Dec. 21) that these discrepancies might arise from the experimental conditions not being sufficiently determined, or the methods sufficiently rigorous. As processes of analysis, they used parallelly—1. Numeration of the corpuscles (by Malassez's own method). 2. Determination of the largest volume of oxygen a given quantity of blood could assume (by M. Grehaut's method). [By globular richness they denote the number of red corpuscles per cubic millimetre of blood; by respiratory capacity, the quantity of oxygen which a hundred cubic centimetres of blood, supersaturated with this gas, liberates in vacuo.]

Before comparing the blood which enters the spleen with that coming from it, it was desirable to find whether the venous blood is always identical with itself; whether it does not, like that of other glands, present globular variation, according as the organ is at rest or in action. M. Cl. Bernard has shown that splenic venous blood has a different aspect, according

as the nerves going to that organ are excited or paralysed; the author therefore studied the globular richness and respiratory capacity in these two states, and it appeared that paralysis produced an increase of these qualities in splenic venous blood, whereas, during excitation there was no increase.

They were now in a position to compare the arterial with the venous splenic blood, and they drew some of each—1. During excitation of the nerves; 2. During their paralysis; 3. Without any action being provoked in the nerves.

During excitation, there is only a very slight difference between the arterial and the venous blood; still, the constancy of the results showed there was a slight increase in the venous blood. There was diminution only in cases in which the arterial blood had previously been taken, and this was no doubt due to the hæmorrhage.

During paralysis, the differences become much more pronounced. If we assume that paralysis of the nerves produces the same effect on the spleen as on other glands, viz., a state of activity of the gland, we are led to suppose that when the spleen acts, the globular richness and respiratory capacity of the splenic venous blood are increased. This augmentation is a phenomenon (the authors think) peculiar to the spleen. In a series of experiments they made on the venous blood of the jugular, the crural, the vein of the submaxillary gland, etc., they found that paralysis of the sympathetic fibres going to the regions whence these veins come is followed by a diminution in the globular richness and respiratory capacity of the blood.

They next sought to ascertain whether the increase in question may go so far as to increase the globular richness and respiratory capacity of the entire mass of blood. The first experiments gave uncertain results; so, to avoid the repeated loss of blood in considerable quantity, necessary for the analyses by oxygen, they limited themselves to numeration of the corpuscles. From five such experiments (of which they give numerical data), it appears that the globular richness at first increases, attains its maximum in from half an hour to an hour, and then decreases. It is remarked, however, that the times were reckoned from the end of the operations, the duration of which was very variable, and the paralytic phenomena were produced during the operation, but their occurrence is not precisely determined; so the figures only give an approximate curve.

M. Picard, in a recent paper, showed that there is normally in the spleen a much larger quantity of iron than that contained in the same volume of blood. Now, if, in the experiments in which the spleen has been paralysed, the proportion of iron be ascertained at various moments after paralysis, it is found to diminish, and it may become very like that in normal blood. Thus, instead of 0.24 gr. of iron per 100 cubic centimetres of spleen (the normal figure), there were found only 0.15 gr., 0.098 gr., 0.053 gr. In the last case (0.053 gr.) the spleen presented an appearance quite characteristic; it was turned back on itself, and flabby, and the tissue, which, on paralysis occurring, was violet-brown, had a rose colour when the analysis was made.

The authors next give some figures from experiments in which splenic arterial blood was compared with venous, no nervous action having been produced experimentally. It is shown that in the physiological state the blood coming from the spleen has a proportion of corpuscles and a respiratory

capacity higher than those of the affluent blood. The increase was constant, but it is capable of varying within wide limits. They propose afterwards to determine precisely the causes of those variations, which are accompanied by changes in the appearance and functions of the organ.

GOLDING BIRD ON THE DISSECTION OF THE EYE.—Mr. C. H. Golding Bird, Demonstrator of Anatomy at Guy's Hospital, says, in the *Guy's Hospital Gazette* of February 10, that the usual methods of dissecting the eye, as described in the text-books of anatomy, though well calculated to display the several component parts, require so much care and manipulative skill satisfactorily to accomplish, that the study of the eyeball is in many cases conducted solely upon paper, and the requisite knowledge of it for examinations acquired from books and lectures. In order to obviate somewhat this state of things, and to render the dissection of the eye as simple as possible, the following instructions have been drawn up, to follow which the most inexperienced dissector need find no difficulty, while nothing of importance for all ordinary purposes will remain unexamined if proper care be employed.

The whole can be studied upon one eyeball, though a second would be advantageous; and the only instruments required—not usually found in the dissecting-case—are a camel's-hair-brush, an ordinary glass slide, and a glass tube drawn into a capillary point, which is preferable to a blow-pipe, however fine.

The dissection is supposed to be carried out upon a bullock's eye. Should the human eye be employed, allowance for the difference of size should be made.

1. Clean from fat and muscles, study the shape and general appearance of the eye-ball.

2. Holding the eye in the left hand, make with a sharp scalpel a small incision into the sclerotic, parallel to, and about half an inch from, the edge of the cornea, of such a depth that the black choroid is seen.

3. Now insert one blade of a pair of scissors into the aperture (piercing at the same time both choroid and retina, being careful not to wound the hyaloid membrane), and cut through all three coats completely round the eye-ball in the lateral meridian, keeping always the same distance from the cornea.

4. Place the eye, with the cornea downwards, in a vessel of water; and, on seizing the optic nerve and making traction, the weight of the vitreous body will cause it to separate into two portions: the anterior, containing the cornea, lens, vitreous body, etc., the posterior, the back part of the shell of the eye. Each will have to be studied separately; and, during the examination of the posterior part, let the anterior remain undisturbed under water.

A.—Of the Posterior Part.—(i.) Fill the cup-like cavity with water and let it rest in the palm of the hand; in it may now be studied the fundus of the eye, e.g., optic disc. (ii.) Holding it in the same position, remove with forceps the retina; the inner surface of the choroid will be exposed. (iii.) Now turn the 'cup' inside out over the tip of the forefinger of the left hand, and, commencing at the circumference, detach, with a camel's-hair-brush moistened, the choroid from the sclerotic. The ciliary nerves and vessels, as fine threads, lying in grooves in the lamina fusca that lines the sclerotic, and pass-

ing to the choroid, are seen during this process. (iv.) Remove the choroid by cutting through its attachment around the optic nerve, and placing it in water, float it on to a slip of glass, with its external (i.e., sclerotic) surface uppermost. With a camel's-hair-brush remove the pigment-cells from the surface, and, on holding it up to the light—still resting on the glass, the *venæ vorticosæ* will be seen. (v.) To complete the study of the sclerotic after the lamina fusca has been examined, divide it longitudinally through the centre of the optic nerve; on the surface of this section, at a point where the nerve pierces the sclerotic, the lamina cribrosa may be seen.

B.—Of the Anterior Portion.—(i.) Whilst resting upon the vitreous body under water, the cornea being uppermost, seize on each side with forceps the cut edges of the sclerotic and choroid, being careful not to include the retina. Raise the eye by means of the forceps thus applied. The vitreous body, lens and capsule, and anterior portions of retina, with the suspensory ligament and canal of Petit, will fall *en masse*, and remaining in the forceps will be the cornea, choroid plexuses, iris, and anterior part of the sclerotic. (ii.) In this latter part, study *in situ* the choroid and its plexuses and the posterior aspect of iris. Then brush off the pigment-cells from the choroid, and detach it from the sclerotic by raising its cut edge with a scalpel; continue this till the point of its attachment to the sclerotic is seen. This is marked by a white line, the ciliary muscle. A cut across in another part will show a transverse section of the same, and at the junction of the cornea with the sclerotic, the aperture of the canal of Schlemm (*sinus circularis iridis*) may be seen. The inner boundary of this canal is formed by the ciliary ligament, or ligamentum pectinatum. (iii.) As a final step, the laminae of the cornea may be stripped off. (iv.) The remainder of the eye (vitreous body, capsule, and lens, etc.) removed from the water, must be turned, so that the lens rest uppermost; and to keep it in this position pass some long pins obliquely through the vitreous body into a piece of wood or cork, on which it is advantageous that the specimen should be placed. On examination there is seen, immediately surrounding the lens, a clear space, and then an exact imprint of the choroid plexuses on the suspensory ligament of the lens (zonule of Zinn), and still more externally the milky-white retina appears, unless it happen to have become detached. (v.) Insert a fine capillary tube into the clear ring surrounding the capsule (i.e. perforate the innermost edge of the suspensory ligament). On inflating, the clear ring will swell into the sacculated or beaded canal of Petit, which is thus seen to be formed in front by the suspensory ligament of the lens, and behind by the hyaloid membrane of the vitreous body. (vi.) Incise the capsule: slight pressure suffices to extrude the lens, while the space left shows how the latter was implanted in the anterior surface of the vitreous body. Rubbing the lens between the thumb and finger will demonstrate its hard central or nuclear portion.

If a lens be kept a few days in alcohol, the peculiar arrangement of its laminae can be seen.

The anterior chamber is the space that exists between the back of the cornea and the front of the iris. The posterior chamber is between the iris and suspensory ligament of the lens.

The positions of the several parts mentioned, and their exact relations to one another, should be examined, if possible, in another specimen that has

been frozen, or hardened in alcohol, by means of an antero-posterior vertical section.

GALTON ON THE EPITROCHLEO-ANCONÆUS, OR ANCONÆUS TERTIUS (GRUBER).—Mr. John C. Galton contributes (*Journal of Anatomy and Physiology*, November, 1874) one of his exhaustive articles, and commences an elaborate essay by expressing himself, in the words of Dr. Burt Wilder, to the effect that 'there is need of more accuracy in the dissection, delineation, and description of muscles, since at present there is great confusion respecting the nature of true muscular integers, and the basis of muscular homologies.'

After recapitulating the works of other observers of muscular 'anomalies,' he records his own experience and investigations as regards this muscle. 'Professor Gruber,' he states, 'though he figures its occurrence in only eleven genera of mammals, exclusive of man, has, nevertheless, found this muscle in no fewer than forty-seven genera, a list of which is given at the end of his supplementary paper.' The author adds to this list, and gives figures of three new genera, viz., *Phascalomys* (*wombata*), *Echidna* (*setosa*), and *Chelopus* (*didactylus*), and gives in addition a figure of the muscle in *Myrmecophaga tamandua*, in which animal it has been already described, but not figured, by Rapp in his well-known monograph, under the name of 'anconeus parvus.'

It would appear from the observations of Mr. Galton and others that the epitrochleo-anconeus is, almost without exception, present and well developed throughout the whole group of Edentata. In the *Monotremata*, the muscle has been found by Professor Wood in the *Ornithorhynchus*, and by Mr. Mivart and the author in two separate species (or varieties?) of *Echidna*, so that it may be almost safely assumed that this muscle is always present in this order. In the *Ungulata* it seems to occur but rarely, or, what is more likely, has not as yet been carefully looked for. M. Gratiolet, though he does not figure it, seems to have recognised it as a factor of the triceps. With regard to the *Carnivora*, *Rodentia*, and *Insectivora*, the members of these three orders are so numerous that as yet no generalisation as to the occurrence of the epitrochleo-anconeus in them has been arrived at, though there seems to be warrant for the statement that this muscle is fairly frequent in all the three groups.

Mr. Galton says 'When we arrive at the *Primates*, we find an evident falling off in the frequency of occurrence of the muscle; for though it is sparingly—certainly not universally—present among the lemurs and lower monkeys, it seems to become lost among the anthropoid apes, and occurs finally in man, though comparatively frequently as a muscular anomaly, still only as an anomaly.'

'Professor Gruber, in the first of his two papers, rightly concludes that the muscle in question is homologous in man and the other mammals, this conclusion being supported by its nervous supply. In man, however, it is sometimes an independent muscle, sometimes a factor of the triceps brachii, while in the rest of the mammalia it is always an independent structure. It is further stated that its function in man is to guard the ulnar nerve and the vessels which accompany it from pressure, and to act as adjutant to the triceps brachii, and to the liga-

mentum cubiti mediale in the way of support of the elbow-joint on its median aspect. In other mammals it acts as an adductor of the olecranon and a supinator of the forearm, being adjutant to the extensor or extensors of the forearm, and serving to protect from pressure either the ulnar nerve and its accompanying vasa alone, or the median nerve and brachial vessels in addition to these.

'In man it has the character of a structure retained from an earlier and lower condition of existence, being, in other words, a *Thierbildung*, while in other mammals it is a necessary and functional mechanical appendage of the elbow-joint.

'This muscle, when present, is generally well developed, rather than weak, in man, and is usually stronger in males, and on the right side, than in females, and on the left side.' Professor Gruber's observations in one month alone amounted to 100 bodies, and, without reckoning difference of sex, the muscle was present in every three subjects and in every four extremities. Professor Wood found the muscle in four male bodies out of thirty-six, a more limited series of observations.

Mr. Galton, though he will readily concede that the epitrochleo-anconeus may in man be occasionally adjutant to the triceps, thinks that it seems to be somewhat of a straining after a *τέλος* to assume that any function other than an active one should be accredited to a muscle rather than it should be simply deemed rudimentary. 'He cannot help regarding the function of an organ but as dependent upon its physical capacity, and could as soon conceive of a ligament taking upon itself the active duties of a muscle, as of the latter enacting the passive rôle of its far less highly organised coadjutor. Better declare at once that a purely muscular slip is functionless, than assume that it exercises the office of protecting a nerve from external injury.

'Seeing, then, that this muscle has been found so frequently in all the lower mammals, and that it is so invariably present in an order—and that, too, one of the lowest—the myology of which, at any rate, has been most carefully studied, while it becomes less frequent among the lower *Primates*, to finally disappear among the anthropoid apes, and only to emerge again occasionally in man as an "anomaly," we have reason for regarding it, as we do such a structure as the supracondyloid process, as a now almost functionally useless heirloom, which has descended to us from very remote ancestors.'

The author concludes his paper by the apt remark, that 'One source of difficulty and of probable fallacy must have occurred to every one, though no allusion is made to it in anatomical writings—in the fact that while perhaps only one member of a species among the lower mammals has been once dissected, hundreds of human subjects—in spite of the indifference manifested in the majority of London dissecting rooms—have been under careful investigation, so that it is possible in the case of the former, instead of that which is normal presenting itself, an anomaly has been stumbled upon, which has forthwith been registered as normal.'

The paper is admirably illustrated on stone by Mr. Galton himself, and shows the epitrochleo-anconeus in *Myrmecophaga tamandua*, *Chelopus didactylus*, *Phascalomys wombata*, and *Echidna setosa*.
EDWARD BELLAMY.

NAUNYN ON THE PRESENCE OF SUGAR IN NORMAL BILE.—At a meeting of the Königsberg (Prussian) Verein für Wissenschaftliche Heilkunde held on March 9, 1874, Herr Naunyn made some remarks on his discovery that sugar is present in the normal bile of rabbits. In all the animals in whom he had made biliary fistulae, he had invariably found sugar in the first drops of bile which escaped; a proof that it must actually exist already in this secretion—the quantity of sugar in the bile secreted afterwards was, however, found to undergo a progressive increase. The importance of these facts in relation to vital (? normal) glycogenesis was also discussed, but the report in the *Berliner Klinische Wochenschrift* (no. 2) January 11, 1875, does not mention the conclusions of Herr Naunyn.

[No mention is made of the tests employed, or of the precautions to avoid fallacies. At present the results of Dr. Wickham Legg's experiments stand in apparent contradiction; unless, after injury of the medulla oblongata, all the sugar escaped in the bile, instead of appearing in the urine.]

W. BATHURST WOODMAN, M.D.

MEDICINE.

TARIOTE ON THE TREATMENT OF SUDDEN INTESTINAL OCCLUSION BY OPIUM.—M. Antoine Tariote, in *Thèses de Paris*, no. 426, 1874, relates two cases which occurred in M. Moutard-Martin's practice, in which appearances of intestinal occlusion that had shown themselves suddenly quickly disappeared under the influence of opium given in large doses. The following draught was given: Thebaic extract ten to fifteen centigrammes; white emulsion, 125 grammes; syrup, thirty grammes; a teaspoonful to be taken every hour until symptoms of narcotism appeared.

M. Moutard-Martin has given as much as thirty centigrammes of extract of opium in one day.

When action of the bowels takes place, the medicine is discontinued. M. Tariote concludes that intestinal occlusions may be divided into two very distinct categories: 1. Intestinal occlusions of slow origin, caused either by simple accumulation of fecal matters, or by paralysis of the intestine or diminution of its size in consequence of the presence of foreign bodies, stricture and compression; 2. Intestinal occlusions which make their appearance very abruptly and rapidly, arising from true internal strangulation, invagination, retroversion or twisting of the intestine. In gradual intestinal occlusion, opium can only be used to overcome the pain or sufferings of the moribund patient. In sudden intestinal occlusion, if there be no well confirmed internal strangulation, opium employed from the commencement, concurrently with applications of ice to the abdomen or blood-lettings, calms the local irritation and the resultant spasm. It also quiets the accidents arising from the general irritation, anxiety, small pulse, chilliness, etc. This treatment may by itself re-establish the circulation of the gases. The re-establishment of the circulation may be advantageously hastened by the administration of a purgative.

HERVEZ DE CHÉGOIN ON NERVOUS HEADACHE AND ITS TREATMENT.—M. Hervez de Chégoïn, in the *Union Médicale* for October 1874, after having

verified the dilatation of the arterial vessels of the encephalon and the face during attacks of nervous headache, considers it as an arterial neurosis. Its starting-point is in the great sympathetic, its precise seat in the nervous filaments which accompany the arteries. Its material phenomena are seen in the dilatation of these vessels, and in the compression it produces on the brain and the other organs, for, in a true fit of intense nervous headache, patients suffer universally, the hands are swollen, the muscles painful, and movements of the joints distressing.

M. Hervez de Chégoïn concludes from these facts that the treatment should be directed against the distress of the nervous system of the great sympathetic, and against the resulting arterial dilatation which in his view constitutes the essential characteristic of the disorder, in which it is necessary to distinguish three things, the intermittent character, the pain, and the arterial dilatation. A special therapeutic treatment, founded on the rigorous appreciation of and reasoned out from these elements of the disease, leads to the good results which have been obtained by the administration of pills composed as follows.

Sulphate of quinine, tannin, each 5 centigrammes (0.75 grain), aconitine, 1 milligramme (0.015 grain) for one pill. One of these pills is given during the day; but some patients, having of their own accord exceeded this dose, take as many as three or four of them daily, with marked benefit. Tannin, in particular, seems to have a special action, which explains the relief obtained by the use of certain substances which, like Paullinia, contain it. This treatment, however, is incomplete, since it does not touch the intermittence nor the pain; these are met by substances contained in the pills for which the formula is given above.

DISEASES OF CHILDREN.

BAIZEAU ON SPONTANEOUS RUPTURE OF THE UMBILICUS AS A CONSEQUENCE OF PURULENT PERITONITIS.—Dr. Baizeau reports (*Archives Générales de Médecine*, Feb. 1875) that twice in the course of years he has attended children who, after attacks of peritonitis, have had purulent effusion which has discharged itself at the umbilicus with resulting cure. Abscesses of the liver, of the iliac fossa, etc., sometimes perforate in the same way with cure; but he considers it rare for the same result to follow in purulent peritonitis, death being the common sequel.

Rilliet and Barthez quote two cases in their work on the *Diseases of Children*, but one of these, he thinks, should be considered as a collection external to the peritoneum. The other, reported by Dr. Aldis in the *Edinburgh Medical and Surgical Journal*, 1847, is briefly as follows. A little girl, seven years old, had acute peritonitis, followed by purulent effusion. Dr. Aldis saw her eleven weeks after the commencement of the acute attack; fluctuation was only made out a month later, and the pus was discharged spontaneously by the umbilicus on June 7, 1846; it continued to run till the 12th, and was quite healed and the child well on Sept. 30.

Another case was published by Bernhardt in the *Medicinische Zeitung*, March 1842. The child, five years old, was attacked with peritonitis on June 6,

1841. Active antiphlogistic treatment was used, but effusion took place; on the 22nd the umbilicus was prominent and red, and on the 25th it ruptured and continued to discharge for some time, but with an eventual cure.

Féréol has collected some similar cases in puerperal peritonitis in adults, but Baizeau thinks it is often difficult in these cases to make sure that the pus is actually in the peritoneum. He gives one case where a trocar was first used, and the matter gathered again and discharged itself by the umbilicus; a fistula remained for six months.

In another case the pus was discharged, both by umbilicus and vagina, and the patient recovered.

Dr. Baizeau quotes at length the two cases he has met with which are briefly as follows.

1. A boy, twelve years old, had general peritonitis in February 1868, with evident effusion, complicated by pleuro-pneumonia on the right side. This was successfully treated, and followed by a large parotid abscess. On March 20, rather more than a month from the commencement of the illness, the abdominal symptoms, which had been masked by the severer chest-complication, again became troublesome, and on April 2 several litres of greenish grumous inodorous pus were spontaneously discharged from the umbilicus. A drainage-tube was put in, passing into the pelvis, and warm-water injections were used. Then a pleuritic effusion occurred, and was punctured with the trocar; and injections, first simple, then iodised, were used here also. The child improved till April 26, when his abdominal pus became very fetid, and rigors and fever came on. Free iodine injections* checked this. They were continued twice daily till May 7, and after this once daily. Meantime the pleural fistula had closed, but was reopened on June 21, as it was prominent, and fluctuation could be detected. A tube was put in and iodine injections used. Eventually in July the patient was allowed to get up and walk about, but the tubes were kept in, the one in the pleura till October 1, and the one in the abdomen till December 20. The child regained perfect health, and suffered no inconvenience from intestinal adhesions. Dr. Baizeau considers that the iodine injections not only prevent putrid changes, but modify the peritoneal secretion. He considers the case one of purulent diathesis rather than infection from the first pus in the peritoneum, and in support of this opinion quotes two other cases of what he considers to be purulent diathesis.

2. The case of a girl, ten years old, is similar to that of the boy, as far as the peritoneal lesion is concerned, the pus discharging again spontaneously at the umbilicus, with immediate relief and improvement of the patient. Dr. Baizeau saw her in consultation and dilated the orifice, and introduced a tube, through which warm-water injections were made night and morning; in a little more than a month the tube was removed, and in six weeks she was able to go to Paris.

Baizeau considers that, without nature's own efforts to get rid of the pus, both children must have died, as most cases do before rupture occurs; therefore he advocates assisting nature by plunging in the trocar at the same place. All cases of purulent peritonitis will not admit of this treatment, on

account of the intestinal adhesions forming pouches, which draining and injection will not reach; but generally in purulent cases, as in purulent pleurisy, the adhesions are soft and scanty.

Infancy and parturition are conditions which favour this natural cure, as the umbilicus in both is soft and yielding. It is, however, possible that a similar cure might occur in other people.

J. KNOWSLEY THORNTON.

SURGERY.

NUSSBAUM ON THE TREATMENT OF UNUNITED FRACTURE BY TRANSPLANTATION OF BONE.—In the *Aerztliches Intelligenz-Blatt*, Feb. 23, 1875, Professor Nussbaum, of Munich, publishes a very interesting and practical clinical lecture on the treatment of ununited fracture, its pathology and methods of treatment, and particularly on the treatment by the transplantation of bone, in complicated gun-shot fractures, resulting in an open false joint, with great loss of bone-substance and necrosis, where the cartilage-encrusted extremities are merely bound together by a long thin tendinous band. As regards the limbs, he confesses that he has had only hitherto one instance in which he has employed the method, but with such a singular amount of success as to afford great encouragement to further attempts in the same direction.

A Saxon lieutenant, twenty-four years old, on July 12, 1870, in the fight at Mars-la-Tour, received a very severe gun-shot wound in the right forearm. The ulna was smashed in the middle, the splinters of bone had necrosed, the periosteum had been destroyed, and subsequent cicatrization had resulted in a false joint, having about two inches and a half of open wound. The two approximating ends of the fractured bone were united by means of a thin fibrous cord. Although the radius was intact, the functions of the bone were so limited, and its abnormal motion so exaggerated, that the patient was invalided. On July 14, 1874, the patient being chloroformed, the false joint was exposed. Both ends of the fractured bone were thin, covered with a pointed cartilaginous process, and slightly united by means of a weak, tendinous false ligament. The pointed cartilaginous extremities and the thin false ligament, being rather in the way than useful, were cut off with strong scissors. Next, the upper surface of the proximal end of the ulna was half sawn through, about two inches and a-half from its extremity, and with a sharp cutting chisel this upper piece of the ulna, with its periosteum, was split off, parallel with its upper surface, yet so that the periosteum of the pointed extremity and of the under surface were not both cut through; thus the detached portion of bone had still a slight nutrient bridge derived from the periosteal covering. Finally, the portion of bone thus detached was so deposited in the gap, that its internal upper surface now became external, the under internal, and the outer surface became the upper one. Had the transplanted portion been turned downwards so that the now upper surface had become the under, the periosteal bridge remaining on the under surface must have been much more dragged upon and torn, and it would have been probable that the blood-communication, through the connecting periosteal slip, might have been entirely cut off.

* The injecting lotion was composed as follows: Tincturæ iodi, xvjss; potassii iodidi, gr. xv; aquæ ad ʒxij. The quantity of iodine was doubled after a time.

[Without the accompanying engraving the description given reads somewhat obscurely, but it would seem that the transplanted portion of the bone obtained its new position by a sort of *mouvement en bascule*.—*Rep.*]

In the gap in which the transplanted portion of bone had been placed, a tolerably deep incision had been previously made into the indurated soft parts, to promote some inflammatory action in the neighbourhood, and to favour the adhesion of the introduced portion of bone. The wound was dressed with carbolised dressing and closed with seven sutures, and subsequently enclosed in a gypsum bandage furnished with a trap-door.

The operation was so successful that in December, 1874, the patient was gazetted to a grenadier regiment.

Professor Nussbaum makes the following remarks on the two great mishaps after fracture, viz., healing bent, or with considerable shortening. Supposing a case is met with within six months, the badly united fracture should be simply broken up again under chloroform, as, before the definitive callus is formed, a refracture is neither difficult nor dangerous.

A linen cloth should be laid on the edge of a table, and the fracture to be rebroken brought quite to the margin. A strong pressure downwards readily breaks the provisional callus, and it is best broken in the direction corresponding with the faulty curve, and should be commenced by extension (for which purpose an extension bandage is most serviceable). Considerable risk is run in refracture, during this stretching, of rupturing some artery adherent to the callus, since the process is never effected slowly but always with a powerful jerk. But if the callus be broken up by bending inwards, the necessary amount of stretching can be conducted slowly and surely. A good position having been obtained, the new fracture can be treated as a simple one.

If six or seven months have passed and the definitive callus have become of ivory hardness and stronger than the sound bone, should any attempt be made at refracture, it would remain intact, and the resulting fracture of the normal bone would render the condition worse than before. Under these circumstances only operation is of use.

Langenbeck employs two processes in the subsequent operative procedure on the bones. After having made a small incision in the skin, he first bores through the callus at the angle; he then enters a small fine key-hole saw into the hole thus bored, and cuts through the bent bones right and left, to such an extent that merely a thin bridge of the cortex of these bones remains intact. The wound is then carefully cleansed. After granulation has taken place and the integument has healed over, he undertakes, as the second portion of the operation, the fracture of the remaining thin cortex, and treats it, by means of a gypsum bandage, as a simple fracture of the bone. The idea is admirable. The object of this partial sawing is, that the mass of definitive callus, which has become as hard as ivory and could itself not be broken up, is readily ruptured when it has been about three parts sawn through, and the fracture can be effected at the 'place of election.' It is a matter of fact that the wounds effected by the boring and sawing portions of the operation produce such inflammatory reaction that the remaining lamellæ thereby become soft and elastic, and so the rest of the operation is rather a bending than a fracture. The most important advantage, however, of Lan-

genbeck's operation, consists in this, that when there is a wound there is no fracture; and at the time when one has to be made and treated, there is no open wound.

The American surgeons reduce the bones to be broken later on, simply by drilling five or six holes through them. Szymanowsky saws a wedge-shaped piece out, three parts of the thickness of which he removes, and after the healing of the soft parts, breaks through the remaining portion. Professor Nussbaum's plan is to avoid the sawdust and *débris* arising from the drilling and sawing operations, by using a fine sharp cabinet-makers' chisel. He chisels through about three-quarters of the thickness of the bone, and then withdraws the chisel, allows the wound to heal, and afterwards breaks through the remaining portion.

[The entire paper is one of great clinical interest, not only as regards Professor Nussbaum's own experience, but of that of others; the reader is therefore referred to the original for greater detail.—*Rep.*]

EDWARD BELLAMY.

SPENCE AND TEALE ON THE TREATMENT OF FRACTURED PATELLA.—Professor Spence of Edinburgh remarks (*Practitioner*) that, though the screw-hooks designed by M. Malgaigne for transverse fracture of the patella are perfect as a mechanical appliance for maintaining the fragments in accurate apposition, yet they have never been very generally used on account of the pain and irritation of the skin often caused by them. Of late years Mr. Spence has adopted the following method of using these hooks without inserting them through the integument, and it answers its purpose admirably. The two fragments of the patella being held by an assistant in as close apposition as the amount of effusion in the joint will allow, a broad piece of strong moleskin adhesive plaster is applied close above the upper fragment: this piece should nearly encircle the limb, and to make it fit round the upper edge of the patella a crescentic piece is cut out of the centre of the lower margin. A similar piece is applied below the lower fragment. Two or three smaller bits are then placed one over the other just where the points of the hooks will be fixed, so as more thoroughly to protect the skin. Care must be taken to have the integuments on the stretch when the plasters are applied, and the latter should be put on some hours before the hooks are inserted, so that they may have time to adhere firmly: this may be secured by keeping a bandage firmly applied over the plasters in the interval.

In the same journal, Mr. McGill describes the mode of treatment adopted in these cases by Mr. Teale of Leeds. He fixes the limb on a straight back splint, or simply places it slightly bent on a pillow between sand-bags, and applies evaporating lotion. He finds that the fragments thus left to themselves, without the use of any hooks, straps, or other apparatus, approximate steadily and naturally. The patient is kept in bed for six or eight weeks, and when allowed to get up, is fitted with a knee-cap of chamois leather. Mr. McGill testifies that the results of this 'expectant treatment' are quite equal to those which can be obtained by any other plan. He relates a case in which the distance between the fragments was thus spontaneously reduced from $1\frac{1}{4}$ inches to $\frac{1}{4}$ inch in less than five weeks. He gives the following explanation of the process. The separa-

tion of the fragments is in the first instance partly due to spasmodic contraction of the quadriceps extensor, which subsides naturally after a few days, and partly to the effusion into the joint which always occurs at the time of the accident; as this is slowly absorbed, the fragments again fall together. Lastly, the fibrous band which is formed between them has, like all other cicatricial tissue, a tendency to contract, and thus completes the approximation.

J. W. LANGMORE, M.D.

MATERIA MEDICA AND THERAPEUTICS.

SPENCER ON TRIMETHYLAMINE IN RHEUMATISM AND GOUT.—The February and March numbers of the *Practitioner* contain a long article on the value of trimethylamine in the treatment of rheumatism and gout, by Dr. W. H. Spencer, physician to the Bristol Royal Infirmary. Trimethylamine is not a new remedy; Dr. Awenarius, a Russian physician, commended it to the notice of the profession twenty years ago as a cure for rheumatism, under the name of propylamine. He had treated with it 250 cases of rheumatism with remarkable success, and considered it little less than a specific. Since then it has, from time to time, been somewhat extensively used on the continent, and its value has been reported on by numerous clinical observers, but the opinions expressed have been most contradictory. The very different results obtained were probably due to the uncertain composition of the preparation which was employed. It was a liquid, of most nauseous odour and taste, which was obtained by the distillation of herring-brine; it contained, besides a variable quantity of trimethylamine, ammonia and ammoniacal compounds and a considerable amount of organic impurity—chiefly animal oil. In fact, it was ascertained by analysis, that the amount of the essential ingredient present in the solutions sold varied from two to fifty-five per cent. Within the last two years, however, the process of manufacture has been greatly improved; and, although chemically pure trimethylamine is not yet an article of commerce, still the solutions now sold are fairly uniform in composition, containing about twenty per cent. of the compound ammonia.

A so-called chloride of trimethylamine is also sold; it is really a mixture of that salt with chloride of ammonium, and, according to Dr. Spencer, is not as reliable in its effects as the solution.

Dr. Spencer has treated sixty cases of rheumatism and gout with these preparations with most satisfactory results; he gives brief notes of some twenty representative cases. He begins generally by giving from four to eight minims of the solution every two hours, gradually increasing the interval as the pains subside, which generally happens on the third or fourth day. Trimethylamine appears to be quite as beneficial in chronic cases of rheumatism and gout as in the more acute. Dr. Spencer relates the history of two patients who had been under treatment for months, and who were cured in three and five weeks respectively from the time when this remedy was prescribed; and they continued well for some months afterwards. In the acute cases also relapses seem to have been both rare and slight.

Trimethylamine in full doses sometimes causes

headache and occasionally, in delicate people, some gastric disturbance and even diarrhoea, but Dr. Spencer has not found these symptoms at all troublesome.

[This remedy has, as above stated, often been quite as favourably spoken of by other observers; it has held its ground in spite of obstacles for twenty years, and the fact that it has never become popular seems to be satisfactorily explained by the unreliable character of the preparation formerly employed. In its present improved state it seems certainly to deserve more attention than it has hitherto received at the hands of English hospital physicians.—*Rep.*]

J. W. LANGMORE, M.D.

OBSTETRICS AND GYNÆCOLOGY.

LÖHLEIN ON THE MEANING OF SUBPERITONEAL ANTE-UTERINE EMPHYSEMA AT DELIVERY.—At a meeting of the Berlin Obstetrical Society, Herr Löhlein related a case which occurred in the Klinik in the year 1873. The woman was thirty-five years old, in labour with her third child; former confinements had been difficult. There was an universally small pelvis; labour was very protracted. Incisions of the os were made, and vaginal injections used. There was ante-uterine emphysema. Perforation of the head and cephalotripsy were performed; the result was fatal. The necropsy showed subperitoneal ante-uterine emphysema, complete attrition of the posterior wall of the cervix, and a perforation of the posterior wall of the bladder. Dr. Löhlein very fully described this specimen, particularly the origin of the emphysema, and coupled with it an observation made in the Poliklinik on a female aged thirty-one, in labour with her fourth child, with a middle-sized pelvis. Various attempts were made with the forceps, which slipped off. There was superficial laceration of the vagina, and tearing of the os. The child was hydrocephalic. Perforation was performed, and followed with cephalotripsy, on account of the extraordinary hardness of the cranial bones. Death took place on the tenth day, with symptoms of peritonitis. A necropsy was not permitted.

In the discussion which followed, Herr Fasbender reported a case as an addition to Löhlein's, where he had discovered crepitation through the abdominal parietes in decomposition of the fœtus. It happened in a woman who had been plugged for some days for placenta prævia. The phenomenon was to be distinctly made out through the abdominal walls; and upon extraction of the child by version, there was found to be emphysematous decomposition of the whole of the covering of the child. The crepitation entirely disappeared upon the birth of the fœtus.

Herr Ebell related that a similar phenomenon, detectable by palpation, was mentioned by Von Olshausen after the entry of air into the veins of the uterus.

Herr E. Martin saw a case in a woman who had been catheterised by a midwife, with a straight instrument. When she was admitted into the hospital an ante-uterine emphysema was recognisable (on the right side and towards the middle. The fœtus was removed by the forceps. The patient died in a few days; and a necropsy showed a perforation of the posterior wall of the uterus and an

infiltration of pus into the right side of the ante-uterine connective tissue. This and Herr Lohlein's case were the only instances he had ever met with of ante-uterine emphysema, out of a great number of instances of rupture of the uterus; consequently he could accord to this symptom only a low diagnostic value.

SINCLAIR ON MANUAL DILATATION OF THE OS UTERI.—Dr. A. D. Sinclair (*Boston Medical and Surgical Journal*) fears that, owing to the variety and perfection of the mechanical contrivances now used for dilating the os uteri, the use of the hand for that purpose is not so much kept in mind as it ought to be. Although sponge-tents, Barnes's bags, etc., are most valuable instruments for inducing premature labour, yet in many cases of emergency, such as the occurrence of convulsions, or of uterine hæmorrhage, when prompt delivery is necessary and the physician is obliged to remain at his post, the use of the hand offers certain advantages. It is always available; there is no delay in searching for or procuring the necessary apparatus; wherever a sponge-tent or India-rubber bag can be inserted, a finger can be introduced. The operator is kept informed as to the precise condition of the parts, and is able to regulate exactly the amount of force necessary to effect dilatation. The operation is exceedingly simple; one finger is first gradually insinuated through the os; then a second by its side, and so on, till at last all five, in a wedge-shaped mass, are inserted into the cervix. Soon the whole hand can be passed into the cavity, but it should be kept opposite the cervix until the os is fully dilated; if this point be not attended to, considerable difficulty may be met with in the subsequent operation of delivery after turning. Dr. Sinclair relates the particulars of several cases in which he adopted this plan, on account of convulsions, placenta prævia, alarming accidental hæmorrhage, etc. One of the patients had only arrived at the fifth month of pregnancy; the others at the seventh or eighth. The time required for the operation may not, even in a primipara, exceed an hour; sometimes the proceeding is completed in fifteen or twenty minutes; but occasionally three or four hours of patient effort are necessary. The use of chloroform or of ether, of course, greatly facilitates the process.

J. W. LANGMORE, M.D.

VAN WETTER AND DENEFFE ON VESICO-VAGINAL FISTULA CURED BY CAUTERISATION.—After referring to the successes of Bezzi of Modena, Galeus, and Cantermann, the authors (*Annales de la Société de Médecine de Gand*) give their own case as a more modest success, in consequence of the number of times it required cauterising and the smallness of the fistula; but they place it, nevertheless, as one among many proving the truth of M. Soupart's words, 'cauterisation cures vesico-vaginal fistulæ.'

In Nov., 1870, E. von C., aged twenty-five, was delivered of a large child; and, the labour not progressing very well, an ignorant woman used instruments, with the result of the immediate escape of urine from the vagina, of which the patient was conscious. The quantity of urine escaping was at first so great that none passed by the urethra; but gradually improvement took place, though urine still ran constantly away. In 1872 she saw Dr. Deneffe, and it was proposed to cure by means of cauterisation and the use of uniting forceps; but her friends frightened her out of submitting to the operation.

In 1873 she entered the service of a lady at Ghent, who was a patient of Dr. Van Wetter, and he persuaded her to submit to cauterisation. At the time the treatment was commenced her thighs, etc., were much excoriated with the constant dribbling. The fistula was situated in the anterior cul-de-sac, *i.e.* behind the anterior lip of the cervix; it was about six or seven millimètres in diameter. The urine flowed from it drop by drop, except when the patient exerted herself at all, and then it jetted out.

The treatment was commenced by cauterising the parts surrounding the opening with sulphuric acid and water, equal parts, applied with an asbestos brush, the application being repeated every fortnight; the fistula gradually contracted until the end of September, when it was less than half its original size, and the patient lost hardly any urine when sitting, and little when lying down; but still a good deal when moving about. A solution of chromic acid and water, equal parts, was now substituted, and used for two months with marked improvement; but the fistula was not cured, and the sulphuric-acid solution was again used. Sometimes she was almost dry for a fortnight, and then worse again; being better always just before menstruation. This was the state all through the summer; and at last the fistula could hardly be distinguished. They then applied a finely pointed stick of nitrate of silver to the fistulous track, and painted caustic potash freely on to the vaginal wall round the fistula. This process having been repeated till August 16, the patient announced that she had been hardly damp for the last fortnight; and the fistulous opening was found to be so small that the nitrate of silver could not be introduced, therefore the caustic potash alone was applied round about. And again on August 30, and September 13 and 27, she declared herself well; and the speculum, when introduced, remained dry. She was seen again in October and November, and had continued well. The cure was thus completed in twenty-eight sittings, extending over fourteen months.

The authors, in remarking on the case, dwell much on the escape from a dangerous and bloody operation, and on the fact that the patient was able to do her work all the time and suffered little. They speak of the great danger of Sims's operation when the fistula is in the anterior vaginal wall (peritoneal zone), and the difficulty when the fistula is deeply seated; also of the dread many patients have of the knife. In conclusion, they urge the general adoption of this plan, and allude to its being within the reach of every medical man, and requiring but few and simple instruments.

[Doubtless there are cases where this plan might be valuable; but the reporter thinks that the majority of patients would prefer a slight confinement to bed, and the small danger of Sims's operation, to such a tedious cure as that arrived at in the case related.—*Rep.*]

J. KNOWSLEY THORNTON.

TOXICOLOGY.

LABBÉE ON THE ACTION OF PHOSPHORUS.—In a series of articles in the *Mouvement Médical* (September and October, 1874) M. Labbée discusses the physiological action of phosphorus, with special reference to toxicology. The symptoms caused by the metalloid cannot be attributed to its direct

action, for uncombined phosphorus, as Ranvier has shown, exerts no appreciable influence on living tissue. Again, the great variety of symptoms and *post mortem* appearances in cases of phosphorus poisoning requires explanation. Lécorché's theory is the most satisfactory one which has hitherto been offered. He divides cases of poisoning by phosphorus into three groups, two of which are perfectly distinct, while the third includes mixed forms. 1. If phosphorus be swallowed during a meal, it undergoes oxidation in the alimentary canal. The resulting phosphoric acid is absorbed, and causes changes in the red corpuscles of the blood, attended by escape of their colouring matter, jaundice, hæmorrhage, and steatosis of various organs. 2. When phosphorus is taken on an empty stomach, phosphoretted hydrogen is produced, partly in the bowel, partly in the blood. The symptoms are almost purely nervous, such as acceleration of the pulse, marked fall of temperature, and convulsions; no jaundice or hæmorrhage occurs; the alimentary canal and the viscera are intact, and yet death ensues very speedily. 3. Sometimes, when phosphorus is taken on an empty stomach, the primary symptoms due to absorption of phosphoretted hydrogen are followed by those which are characteristic of poisoning by phosphoric acid. This must be attributed to the prolonged survival of the patient; there is time for the phosphoretted hydrogen in the blood to become converted into phosphoric acid, the effects of the latter compound being superinduced upon those of the former.

M. Labbé proceeds to insist on the superiority of the evidence furnished by morbid anatomy over that derived from chemical analysis in cases of suspected poisoning by phosphorus. The Society of Legal Medicine was requested, by a French tribunal, to decide whether an expert might legitimately infer poisoning by phosphorus from the presence of abnormal quantities of phosphoric acid or phosphates in the matters submitted to analysis, and this in the absence of any trace of free phosphorus, and of the characteristic structural lesions. The question, as might have been anticipated, was answered in the negative.

Personne's method of treatment is next alluded to. He found that the oxidation of phosphorus was prevented by essence of turpentine. Several cases of recovery, after considerable quantities of phosphorus had been swallowed, have been ascribed to the use of this antidote; but Depaire, in his report on this subject to the Belgian Academy of Medicine (April, 1874) asserts that turpentine failed to arrest, or even to modify, the symptoms and anatomical changes due to phosphorus-poisoning in dogs. Labbé accordingly concludes that it would be unwise to trifle with a remedy of doubtful value, and recommends the practitioner to rely on emetics, especially on sulphate of copper, in his treatment of these cases.

E. BUCHANAN BAXTER, M.D.

REVIEW.

Therapeutic Means for the Relief of Pain: Fothergillian Prize Essay. By J. K. SPENDER, M.D., pp. 226. London: Macmillan & Co. 1875.

Dr. Spender is well known as an able practitioner, but we question whether this work is quite worthy of him. Perhaps prize essays as a rule are not calcu-

lated to bring out the best work of a man; yet the subject is a tempting one; the title sounds attractive; in MS. perhaps the work read better than the average essay. We think it a pity that the author was not content with this moderate success.

In chapter 4, all that he really has to tell us is that opium relieves pain in various parts of the body; but why does he put it thus? 'I pass to the subject of disease in the abdomen, and we have only to study any monograph to find that the therapeutic history is in a large degree a song of the triumphs of opium' (p. 43). And again, 'The bare mention of that terrible disease, peritonitis, is suggestive of the siren lullabies of opium.' At the end of sixty pages, which might with advantage have been compressed into six, we fancy that the author himself begins to grow tired of elaboration and quotation. 'In relating the capabilities of drugs to allay Pain, it would be wearisome and quite superfluous to travel over the identical ground,' etc. And the rest of the book is little more than an enumeration of medicines, with a sprinkling of cases and extracts from the already well-known papers of others.

Of course there is evidence of a fair amount of reading. Anstie, Garrod, and others, are laid freely under contribution; but we fail to find anything sufficiently valuable or original to justify the putting forward of the volume. If there be anything special, it is perhaps the stress laid upon the value of small and frequently repeated doses of antimony and morphia in relieving pain and inflammation. But this Dr. Spender had already published in the *British and Foreign Medical Review*, in an article which really we prefer to his book.

We suppose it possible that his pages may be of use to some who read little, or who do not possess any modern standard treatises on therapeutics; but we could readily name half a dozen such treatises, in which all the practice that can be taught in words is already set down in a far more satisfactory manner than in the work before us. We repeat that we have no doubt it amply merited the medal of a society, but we regret that it has courted the criticism of the profession.

NEW INVENTION.

MATHER'S NEW BREAST-EXHAUSTER.—We have received a specimen of the new breast-exhauster lately introduced by Mr. Mather. This instrument is no doubt a great improvement upon those already in use. The novelty consists in the addition to the teat or mouthpiece of a valve, which freely permits air to be withdrawn, but prevents its return into the vessel. By this means the air is gradually exhausted in the receiver, and the flow of milk is kept up with little effort and entirely without pain. To facilitate removal, the neck of the receiver opposite the nipple-shield is pierced by a small opening; this must be covered with the finger while the instrument is in use. The introduction of the valve greatly diminishes the force of suction necessary to promote the flow of the milk from the breast, and also allows the power exerted to be regulated with nicety, so that the breast may not be drawn too far into the bell of the receiver. On this account the instrument is especially suited to cases of sore or cracked nipples, or to any case where great tenderness of the breast necessitates delicate manipulation.

CORRESPONDENCE.

DR. RUMSEY, F.R.S.

(To the Editor of the LONDON MEDICAL RECORD.)

SIR,—Dr. Henry W. Rumsey, of Cheltenham, has just retired in consequence of a severe attack of illness, which disables him from continuing his practice; and it is thought by many that this is a favourable opportunity for expressing their appreciation of his services to the sanitary cause, to the profession, and to the public. A sketch of his labours, extending over the greater part of his career, and of his consequent claims, has been drawn up, and is now in circulation.

I first met Dr. Rumsey before a Committee of the House of Commons, pleading at once for the poor and for the poor law medical officers. He was associated with his intimate friend, Robert Ceely, of Aylesbury; and to the energetic action of these two men, acting in concert with the Provincial, the British Medical Associations, and the press, the progressive improvement in the medical relief of the poor owes its origin. He took an active part in the endeavours of those who were seeking to put provident societies on a sound footing. Dr. Rumsey wrote on the health and sickness of town populations (1846); and in the year 1856 published his classical volume of *Essays on State Medicine*; which was followed year after year by a series of striking papers on sanitary science and administration. Dr. Rumsey is a scholar; and his writings, remarkable for clearness of exposition and originality of view, have undoubtedly contributed to impress the Legislature with its present views of the importance of public hygiene, which, like every good cause, has had to encounter hostility. If a sagacious Prime Minister has given the world the new reading of *sanitas sanitatum*, Dr. Rumsey has some claim to the credit of party enlightenment. But Dr. Rumsey began his labours in an age of indifference for the cause, which is only beginning to triumph when he is cruelly struck down.

Some persons held that public health is an affair that can be handled by nuisance inspectors. Dr. Rumsey, on the contrary, saw clearly that the public health could be best dealt with by specially educated medical men, well versed in science; and it is his great merit, that in the General Medical Council, as well as elsewhere, he sought to obtain a special qualification from the examining bodies for State Medicine. This would be in all time to come a guarantee of competency to the public; while it would open great careers to eminent State physicians, proceeding on the lines laid down by the Father of Medicine. One of the last papers I heard by Dr. Rumsey was on this very subject.

Dr. Rumsey, its chairman, was in constant correspondence with the joint Committee of the Social Science and the British Medical Associations; he spared no labour, and frequently at the sacrifice of his professional time came to London. His correspondence on public matters was unintermittent. Among many other avocations, Dr. Rumsey was a vigilant sanitary critic. He criticised freely the Legislature, the Government, the Public Offices, including that with which I am concerned, and the Registration of vital statistics. On some of these subjects he was, I think, wrong; at least I differed from him; but I do not hesitate to say that his criticisms were often beneficial, were animated by public spirit, and were characterised by fearless honesty of purpose.

During his career Dr. Rumsey has received many honorary marks of the appreciation of the profession; and has been recently elected a Fellow of the Royal Society. But at the close of thirty-seven years, full of his labours for public objects, and professional interests, in which he has expended much and received nothing, it does appear to me that if Dr. Rumsey was still in the vigour of his life the time has come when some substantial testimonial

might be presented to him. Such a step could only tend to encourage men to devote themselves to the public service. And now Dr. Rumsey, after climbing the steep side of the hill, is smitten down before he can enjoy the full fruits of professional fame, his claim is enhanced. He is a man of whom we may be justly proud. And the appeal now made in the name of that noble fraternity which binds the profession together as one body cannot be in vain. He will receive the crown he has won at last.

The British Medical Association and the Social Science Association, at the meetings of which Dr. Rumsey has presided in the health sections, will probably turn their admirable organisations to account in favour of the movement.

A central committee has been formed in London, including the most eminent men, and now it is proposed to invite leading members of the profession in the provinces to establish corresponding committees; their support will, I doubt not, be afforded. Dr. Rumsey himself, practising in the provinces, was one of their brilliant ornaments, and one of the most strenuous asserters of their claims and rights.

General Register Office, WILLIAM FARR,
Somerset House, Chairman of Central Committee.
London, March 12, 1875.

MISCELLANY.

M. WALLON, the French Minister of Public Instruction, has appointed M. G. Pouchet, the son of the celebrated advocate of spontaneous generation, to fill the room of M. Paul Bert, professor of physiology to the Sorbonne, as the latter, being a member of the National Assembly, cannot attend to his professorial duties.

A MEDICAL FICTION.—A curious work of fiction is now in course of publication at New York. It is entitled *Medizinische Novellen*, and is by Dr. Bernhard Segnitz, a German physician. These tales, which will recall the memory of Mr. Warren's *Diary of a late Physician* to some of our older readers, relate to measles, catalepsy, icterus, delirium tremens, intermittent fever, and chloroform suicide. The subjects certainly appear unpromising, if original, as foundations for effusions intended to amuse our lighter hours. The lovers of 'sensation,' however, will find in these volumes abundant matter to their taste. For instance, in the story on delirium tremens, the heroine is the subject of the disease; she is a person of princely blood, who proposes marriage to her cousin, fires a revolver at him when he declines the honour, and buries her grief in libations of brandy. *Mania a potu* results, of which the doctor cures her, and by the personal influence of the prince regent, her cousin accepts her hand, and they are presumably happy ever afterwards.

CLAY EATERS.—Herr F. K. Leusinger, in his *Travels on the Amazon and Madeira*, speaks of the appetite for clay shown by the inhabitants of the virgin forests traversed by these rivers. This propensity is common to all ages from childhood to old age, and is so strong that the prospect of a miserable and dreadful death cannot withhold them from satisfying this morbid taste. It is not uncommon to see amongst the negroes employed on the coffee and sugar plantations an unfortunate being working in the heat of the day with an iron mask over his face; this is a clay-eater, whom it is sought to save from his deplorable propensity by this means, and who is never allowed to take off his mask except under proper superintendence. This taste, however, is not peculiar only to man in these regions. Many animals, with the exception of the jaguars, and even birds also show it, of which advantage is taken for hunting purposes. The hunter has only to place himself in ambush near a clay pit, on a moonlight night, and he will soon have

plenty of sport among the wild boars and roe-deer, as well as the jaguars, attracted, not by the clay, but by the desire for a living prey.

NUMBER OF INQUESTS.—The *British Medical Journal* for March 13 calls attention to the number of inquests held at the present time. It remarks that the condition of life in England has so completely changed since the office of coroner was instituted and the statutes regulating it became law, that it has become a moot question whether a good many unnecessary inquests are not now held. The object of the inquests was undoubtedly to discover crime, with the object of punishing it, and with a view to its prevention. A few centuries ago, when the state of science was far different from what it is now, 'sudden death' was considered a sufficient ground for the holding of an inquest. Dr. W. Farr, in a letter on the causes of death in 1872, published in the last annual report of the Registrar-General, says: 'The mere fact that death is sudden is a ground for medical inspection, but not necessarily for an inquest; and there are many violent deaths of which a medical inspection may ascertain the cause without moving the apparatus of the inquest, there being no more suspicion of crime in such cases than there is in deaths from fever, pleurisy, or consumption.' In 1872, the number of inquests held in England and Wales was 25,705, at a cost of 78,535*l.*, or rather more than 3*l.* per inquest. The general proportion of inquest cases to total deaths has exceeded 5 per cent. in each of the three last years, 1872-4. It appears, therefore, that an inquest is held in one of every twenty deaths that occur. In the eighteen large English towns for which weekly returns are published by the Registrar-General, the percentage of inquest cases to total deaths during 1874 ranged from 3·3 and 3·6 in Bradford and Hull, to 7·2, 7·6, and 7·9 respectively, in London, Birmingham, and Manchester. The average proportion in the eighteen towns was 6·3 per cent., whereas in the whole of England and Wales it was rather more than 5 per cent. It is natural that the proportion of inquest cases in towns should exceed that in rural districts, in consequence of the greater frequency of deaths from violence; but this will not explain the wide difference in the proportion of inquest cases in the large towns above mentioned. In Bradford and Hull, the percentage of inquest cases exceeded that of deaths from violence by only 0·8 and 0·5; whereas in London the deaths from violence were 3·6, and the inquests, 7·2 per cent.; in Birmingham, 4·1 and 7·6; and in Manchester the violent deaths were 3·1, and the inquest cases 7·9 per cent. Assuming that inquests are held in all cases of death from violence, in each seventy-nine inquest cases in Manchester, the cause of death in forty-eight was other than violence; whereas of seventy-two inquest cases in Hull, only ten proved to be deaths from natural causes. The question to be answered is, Are too many inquests held in Manchester, or too few in Hull? Such an anomalous state of things as to the proportion of inquests held is decidedly undesirable; and it would be well if some code of regulations could be drawn up, or law enacted, to secure greater uniformity of system among coroners, without detracting from the dignity and independence of the office by too far weakening its discretionary power.

THE COMPARATIVE DURATION OF LIFE IN MEN AND WOMEN.—Mr. Cornelius Walford, F.S.S., made some interesting statements on this subject in a paper which he read on February 22, at the Institute of Actuaries. Dr Halley, of Breslau, who wrote in 1693, evidently supposed both sexes to be equally long lived. Maitland, in his 'History of London,' published in 1739, was of opinion that the old idea of there being more females than males in the world was a fallacy, the christenings of boys within the bills of mortality being 3 per cent greater than those of girls. Kerseboom, in his investigations into the mortality of Dutch annuitants in 1742, separated the male from the female lives; but he does not appear in his tables to have noted any difference in their relative longevity. Four years later, M. Deparcieux, in his observations on

the nominees of French tontines, lays it down that the 'expectancy of life' is greater in the female than in the male at all ages; but he does not determine the precise ratio. It was the 'Equitable' society, which in 1762 first approximated to the truth of the matter, by making a distinction of rates of premium for each sex, and taking no female lives under fifty years of age as insurers except at special rates. Dr. Price, in 1771-3, speaks incidentally of 'the greater mortality of males as compared with females' as being generally acknowledged; and Brand, speaking of the 'Amicable,' says that in it 'the life of a woman as compared with that of a man, is of the same proportion as two to one.' Mr. T. Chester, in 1783, asserted that the difference between male and female lives was in 'favour of the latter; and the same rule was laid down in some Swedish tables constructed by Dr. Price about the same date. Mr. Walford quoted the statements of the Carlisle tables, of the Parliamentary Committee of 1827, of M. Quetelet, of Messrs. Bailey & Day, of Mr. Finlaison, etc., as on the whole showing that from first to last the expectancy of life is greater in the female than in the male sex. The same result was arrived at from certain statistics of uninsured lives among the higher and wealthier classes, which were obtained and tabulated in 1874; a result which may be expressed in the following terms—viz., that 'at every age the aggregate mortality from birth up to such age is greater among males than among females; and that out of the same number of each sex, born alive, fewer males than females survive to any given age.' On the whole the above statement is confirmed, added the reader of the paper, by the experience of foreign countries, both on the Continent and in America. But this must be understood with some qualification; for, while the expectancy of life is greater generally among women than men, most offices find that of a given number of insured lives more women die than men. This, however, was to be accounted for by the fact that whereas male insurers are drawn from all classes, only one small class of females, as a rule, seek to insure their lives—namely, women in a state of actual or expectant pregnancy; and here, as he believed, lay the secret of the anomaly which had been observed.

WEDNESDAY, APRIL 7, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

MEYNERT, HUGUENIN, AND LUYA ON THE MECHANISM OF THE CENTRAL NERVOUS SYSTEM.*

In the past few years, two notable attempts have been made to declare the mechanism or interior plan of structure of the central nervous system. The first in order of time was that of Luys, the title of whose work will be found below, and the last is that of Professor Meynert, of Vienna.† Both have had, and now have, students of and adherents to their views. Especially is this true of the latter. The work of Dr. Huguenin, of Zürich, the title of which stands at the head of the list, is by one of Professor Meynert's students. But he is something more than a student. He would seem to be a critical expounder of the system of his master, from whose views he has not hesitated, in many respects, to dissent. It is to a brief survey of the contents of the first few chapters of this work that we would, in this article, more particularly invite the attention of the reader. But this will hardly be possible without describing in outline the system of Luys, as well as Meynert's, whose system is adopted in the main by Huguenin.

Luys followed the plan of making a vast number of sections of the prepared nervous substance of all parts of the central nervous system, and of studying them under low powers of the microscope, in due order, and then of combining the items of information obtained in this way, so as to form a scheme of distribution of the histological elements of the same. The following is an outline of his system.

First, we have the masses of the central nervous

III. M. J. Luys: *Recherches sur le Système Nerveux Cérébro-spinal, sa Structure, ses Fonctions, et ses Maladies*. Par J. Luys. Paris, 1865. Atlas de Quarante Planches.

system, the ganglia, variously divided, consisting chiefly of nerve-cells. Belonging to these, and completing the nervous apparatus, we have, according to M. Luys, four great systems of nerve-fibres, besides simple commissural fibres: two of them are called converging. These are called respectively inferior and superior. The former includes the whole of the so-called sensory peripheral nervous system. All cerebral and spinal sensory nerves (not to mention the sympathetic) throughout, belong to this class, both in the spinal cord and out of it. From all parts of the body, with few exceptions, fibres of this class converge on the spinal cord and ganglia at the base of the brain, more particularly the latter. This, as we have said, is the inferior converging system.

The superior converging system consists of all those fibres which begin in the cells of the cortical substance of the hemispheres, and converge toward the base of the brain on certain ganglia there situate.

As the inferior converging system of fibres is destined to convey impressions from all or nearly all non-nervous parts of the body—impressions physical in their nature or origin—so, on the other hand, the superior converging system of fibres is destined to convey impressions made at the peripheral end of this system of fibres, perhaps mental instead of being physical in their nature and origin. Both these systems converge at the base of the brain. Both systems at their periphery have peculiar forms of apparatus, suitable for receiving the impressions adapted to them. On the one hand, we have the peripheral apparatus of vision, hearing, smell, taste, touch, and so on; on the other the apparatus of thought, lodged in the cortex of the brain.

The other two are the diverging systems of fibres, also called inferior and superior. The former—the inferior diverging system of fibres—proceeds from the motor cells of the cord and ganglia at the base of the brain, and leads outwards from these centres towards the periphery of the body. The motor fibres to the muscles, and to all glandular structures whose actions are normally influenced by the nerves, belong to this system.

The latter—the superior diverging system of fibres—leads from certain of the ganglia at the base of the brain upward to the cortical substance of the hemispheres. The fibres of this system are destined to convey impulses or impressions from the great sensory ganglia upwards to the cells of the cortical substance, which latter are in this way excited to action, just as truly as the motor-muscular nerves convey impressions to the muscles that make them act.

To these must be added certain tracts of commissural fibres like those of the corpus callosum.

Such, in broadest outline, is the system of Luys. To carry a view of it out into detail would not be possible here, nor consistent with our present plan, the aim in which is to give simply an outline.

The work of Dr. Huguenin opens with a short but very excellent chapter on the 'Development of the Brain and Spinal Cord.' The next is devoted to a 'General Scheme of the Structure of the Brain and Spinal Cord.'

This is the part of the work to which attention is chiefly invited in this notice, in connection with corresponding parts of the memoirs cited from Meynert. If we should take the brain and remove the hemispheres, excepting the ganglia at their base, and then should remove the cerebellum, we would have

left above the spinal cord proper, what is called in the system of Meynert, the 'brain-stem' (*Hirnstamm*), or in more common language, the 'peduncles' of the brain. It includes, in the system of Meynert, the crura cerebri, the corpora striata, the thalami optici, corpora quadrigemina, and the whole of the medulla oblongata. Spread out above this is the 'brain-mantle' (*Hirnmantel*) or cortical layer of the cerebral hemispheres.

After making the ordinary macroscopic distinction of the nervous substance of the nerve-centres into the white and grey, Dr. Huguenin follows Meynert in dividing the grey matter of the central nervous system into four 'categories' or groups. They are as follows.

1. 'The superficial grey substance of the hemispheres out of which, collectively, the descending fibres take their origin.

2. 'The grey substance of the great ganglia at the base of the brain. Here it is to be remarked that these masses are to be divided into two categories, or those which stand in connection with sensible or sensitive surfaces, and those which do not. This lays down the radical functional distinction to be made between the ganglia of the second category, viz., motory and sensory.

3. 'The so-called "grey tube" or canal (*Röhrengrau*), of Meynert, an immediate production of the "medullary tube" and the "brain-sac." It invests the central canal of the brain and spinal cord, which extends from the infundibulum through the aqueduct of Sylvius, and the space (*calamus scriptorius*, *Rautengrube*) on the posterior surface of the medulla oblongata, corresponding to the fourth ventricle, and so on through the whole length of the central canal of the spinal cord, and is known as the grey substance of the medulla oblongata and spinal cord.

4. 'The grey substance of the cerebellum and its appendages, which has manifestly a structure wholly peculiar, and is devoted, without doubt, to peculiar functions.

'These different categories of grey substances stand connected together by means of a vast number of bands of nerve-fibres,' etc. To understand Meynert's scheme of the nervous system even in its outline, it is necessary to fix these categories of grey nerve-substance clearly in mind.

Dr. Huguenin next proceeds to declare the great systems of fibres which, according to Meynert, connect the masses of grey nervous substances with each other in the order of their importance, and in view of the functions they are known or supposed to subserve.

To survey the above-mentioned system of fibres we must begin with the first category of grey matter, or the cortex of the brain.

Extending from the cells of every part of the inner surface of the cap formed by the cortex of the cerebral hemispheres, are vast numbers of fibres, which are divided at once into two classes :

1. Those which serve to connect different parts of the same hemisphere together, or of the opposite hemispheres, and which are called the 'association or arch system,' (*Bogensystem*). These fibres exist for the purposes of securing concerted and harmonious action between different parts of the brain. They are the commissural fibres of our older works.

2. Those which do not terminate as they began, in the cells of the cortex of the hemispheres, but converge at the base of the brain on certain ganglia there situate, in the cells of which ganglia the fibres

in question chiefly terminate. These fibres include the superior converging and diverging systems of Luys. They constitute the 'projection-system' No. 1 of Meynert. The fibres of this vast 'projection-system' are wholly confined to the interior of the cerebral hemispheres, and constitute what is called ordinarily the white or medullary matter of the hemispheres.

At one end, as we have seen, these fibres terminate in the cells of the cortical substance of the brain ; at the other, with certain exceptions, in the great ganglia at the base of the hemispheres.

Leaving the grey substances of the first category, or cortex of the cerebral hemispheres, we will descend to the great ganglia at the base of the brain, or category of the second kind. These are not only the lower termination of the fibres of the first projection-system, but they constitute the origin of the fibres of projection-system No. 2. The number of fibres composing this second system is very small as compared with that of the first system already described. Hence these ganglia of the second category constitute a 'reduction-region' (*Reductionsgebiete*), or a medium for reducing the number of fibres that shall pass downward into the medulla oblongata to constitute the second projection-system. In other words, the fibres which descend from the cortex of the brain, and are projected into the upper surface of the great ganglia at the base of the brain, terminate as a rule, with certain exceptions, in the cells of these latter ganglia. It is only by means of the cells of the ganglia (of the second category) that the fibres of the first projection-system become connected with those of the second projection-system. Hence the ganglia of the second category are called 'interruption-masses' (*Unterbrechungsmassen*). The fibres which enter the ganglia in question are interrupted in their course as fibres by the interposition of cells. The cells receive a vast number more fibres from the first projection-system than they give off to the projection-system No. 2. Hence this region, as already remarked, has been called by Meynert, a 'reduction-region' (*Reductionsgebiete*), etc.

The ganglia of the second category are the thalamus opticus (*Sehhügel*), corpus striatum (*Streifen-hügel*), the nucleus lentiformis (*Linsenkerne*). These three ganglia lie in pairs, separated by the space called the third ventricle. Finally we have the corpora quadrigemina (*Vierhügel*), lying behind the first mentioned ganglia, and, unlike the others, closely united in the middle line.

The second system of nerve-fibres, (projection-system No. 2,) springs from the aspect of the ganglia, just mentioned, opposite to that of the cortex of the cerebral hemispheres. Some of the fibres of projection-system No. 2, terminate in various points in the medulla oblongata, such as the centres for the motor nerves connected with the special senses, or for the control of peculiar muscular groups, such as the centres for the facial, or hypoglossal, or pneumogastric, or other nerves ; or in various parts of the gray central substance of the spinal cord (*Höhlengrau*), all the way from the medulla oblongata to the lower end of the spinal cord.

The great mass of the fibres of this second projection-system, after they depart from the ganglia at the base of the brain, descend, under the name of the crura cerebri or peduncles of the cerebrum. At this point, a capital feature of Meynert's system comes in. He divides the fibres of projection-system No. 2 into two classes : first, those which

arise in the nucleus lenticularis and the corpus striatum, and convey the orders of the will downward toward the muscles; and, second, those fibres which proceed downward from the thalamus optici and the corpora quadrigemina, and do not convey the orders from the will, but reflex impulses, of which the ganglia just mentioned are the seats.

These two great divisions of the 'brain-stem' (*Hirnstamm*), are called respectively, the 'basis cruris cerebri,' and the 'tegumentum cruris.' Let it be remembered these two divisions of the 'brain-stem' contain the fibres, both sensory and motor, of projection system No. 2. The fibres of the 'basis cruris cerebri,' which convey downward the orders of the will, from the corpus striatum and ganglionic masses associated with it, as they pass downward, terminate below, as already said, some of them in special motor centres, lodged in the pons Varolii and medulla oblongata, to be switched off in various directions, while the bulk of them pass lower down, and decussate, probably, in the medulla oblongata, and enter into the opposite lateral column of the cord, to terminate finally in the cells of the gray matter of the spinal cord, at various points, even down to its lower part it is probable.

The fibres that compose the 'tegumentum cruris,' pass downward also, and as they do, partly, at least, enter the antero-lateral column of the spinal cord of the same side, and, in part, cross over in the medulla oblongata, to the opposite half of the cord. They terminate, at various heights, in the grey matter of the medulla oblongata and cord. Whether the fibres descending from the 'basis cruris' and the 'tegumentum,' terminate in different tracts of the grey matter of the cord, is still, in a measure, a matter of inference. So much, then, for the fibres of projection-system No. 2, which serve to connect the great ganglia, at the base of the brain, with the small ganglia in the pons, medulla, and the grey central matter of the whole length of the spinal cord.

We repeat, that the fibres which pass down in the basis cruris cerebri, in the manner described, convey the orders of the will on their way from the cortical substance of the hemispheres toward the voluntary muscles, and that the fibres which pass down in the 'tegumentum cruris' become the conductors of reflex impulses, which are excited by sensory impressions, transmitted to the optic thalami and corpora quadrigemina by means of the cranial and perhaps other sensory nerves.

So much, in brief, as to the disposition of the fibres composing projection-system No. 2. Next in order, we have the projection-system No. 3. It is composed of all those fibres which connect the grey matter of the spinal cord and medulla oblongata with the non-nervous, motor, and sensory parts of the body, such as muscles, membranes, etc., and which takes the name, commonly, of the peripheral nervous system. It embraces both the sensory and the motor nerves of the whole body, excluding, perhaps, some of the nerves of special sense.

A few words must be said as to the grey matter of the spinal cord. In the opinion of Meynert, the grey matter of the cord had originally the form of a prolonged tube (*Höhlengrau—Röhrengrau*), of course hollow in its interior. This tube extends from the lower end of the cord, upward to the medulla oblongata, at which point it is laid open, from behind or above, so as to display its interior, constituting what is called the floor of the fourth ventricle, and thence upward

and forward, along in the base of the brain, through the aqueduct of Sylvius and the third ventricle, lining its sides and floor, and as far forward as the infundibulum, where it terminates. This tube receives the fibres of projection-system No. 2, and gives off the fibres of projection-system No. 3. About its upper or cephalic end, and in close relations therewith we have grouped the special ganglia of the second category of grey matter, already described.

The fibres of projection-system No. 3 exceed in number those of system No. 2, in a degree quite equal to those of projection-system No. 1. The grey matter of the 'medullary tube' constitutes a region in the central nervous system, for the multiplication of nerve-fibres, in contrast with the ganglia of origin of the fibres of the second projection-system, which constitute, as we have seen, a 'reduction-region' (*Reductionsgebiete*).

To restate, briefly, the general plan of structure of the central nervous system, as set forth by the school of Meynert: We begin with the grey matter (cells) of the cortex of the cerebral hemispheres, and (putting the association-system out of sight for the moment) find a great system of nerve-fibres rising therein, to converge on certain great ganglia at the base of the brain, in which ganglia the fibres, as a rule, terminate, by becoming connected with nerve-cells. The fibres are thus interrupted in their course, and, by this means they are enabled to form, through the agency of the cells, a complicated system of connections with special groups of nerve-cells in various directions. The ganglia in which this interruption of the continuity of fibres is effected are called, in Meynert's scheme, 'interruption-masses' (*Unterbrechungsmassen*). From these ganglia a second set of fibres spring, which pass downward in the basis cruris and tegumentum, to terminate in the cells of the grey medullary tube, which occupies the axis of the spinal cord and parts above. This is projection-system No. 2.

Then the cells of the grey medullary tube give off the peripheral nerves, both sensory and motor, to constitute the projection-system No. 3.

Now we come to projection-system No. 4, or that which connects the grey matter of cerebellum (fourth category of grey matter), with the three other categories of grey matter, namely, the cortex of the cerebrum, the ganglia at the base of the brain, and the grey medullary tube of the cord, etc. As regards the cerebellum, Meynert looks upon it as an apparatus wholly peculiar, as indicated by its position and structure, and deserving a separate consideration. The fibres that pass or are projected out of the cerebellum are divided into three pairs of bundles, called crura or peduncles, which, as is well known, are named according to their respective positions—superior, middle, and inferior. The former connect the cerebellar hemisphere of one side with some part, at present unknown, of the cortex of the hemispheres of the opposite side. The middle crus or bundle passes forward into the pons Varolii, where its fibres enter into connection with nerve-cells that belong to the second category of grey matter at the base of the brain, and the third bundle passes forward and downward to terminate in the cells of the third category of grey matter, represented in the grey medullary tube of the cord. This third bundle from the cerebellum, before it enters the cord, divides into two parts. The first (corpus restiforme) becomes continuous with the anterior column of the spinal cord, perhaps of the opposite side, while the second

(funiculus cuneatus and gracilis) by a very circuitous course, becomes continuous with the posterior column of the spinal cord.

So much for the system of Meynert in outline, not only as set forth by himself, but by Dr. Huguenin, who adopts Meynert's views in the main.

As regards the word 'projection,' as applied to the different classes of fibres, it would seem to have one of two significations, perhaps both. It either has reference to the fibres themselves as being 'projected' from the masses of grey matter in which they take their origin, or, what is more likely, it has reference to the centripetal impulses, which, made at the sensory surfaces, pass inward until they arrive at the cortex of the cerebral hemispheres, against which they are finally 'projected,' either to be retained there through some incidental material change in the cortex, or to be reflected back again towards the periphery, for purposes of motion.

As regards the function of the cortex in general, Meynert holds it to exist—at least we so understand him—for the purpose of storing up in some way the ingoing 'impressions' projected into it. He does not consider it a part of the nervous system, for the origination of impulses from the activity of the mind and of communicating the same to other parts of the nervous system.

There is one point in this connection that we will mention as possibly having some bearing on this subject.

Meynert holds it as at least probable that the retina of the eye, as well as the olfactory bulb, is essentially a detached portion of the cortex of the cerebral hemispheres. If so, the way in which these portions of cortex receive their impulses may throw some light on the source of the impulses that arise in the cortex of the hemispheres. Take the retina for example. In this case, it would seem, if it is to be regarded as the analogue of the cortex, that its impulses are received directly from the outer world, light being the agent for producing them. It takes cognisance of the wonderfully delicate pulsations of the 'ethereal medium,' of which light is supposed to be a result. The retina does not exist for 'storing up' the pulsations in question, but for receiving and transmitting them. If this is so, why may we not infer that the cortex is similarly constituted? But, if so, where do the impressions come from that are to be compared with those made on the retina? Some would answer readily enough, from the free and independent activity of the mind, the will, but not so Meynert. But we must pass by reflections like the above, to be indulged at another time, if at all.

It is entirely apart from our present purpose to enter at this time more into details, to do which satisfactorily would require a long series of articles. For the views of Meynert are most carefully worked out, in view, not only of the nature and visible disposition of the histological elements of the nervous system, as seen by the microscope in man, and all classes of lower animals duly compared, but in view of the outer form and gross appearances generally of the nervous system, of its mode of development, of the results of physiological experiment, and of pathological observation. It may be readily imagined that where so much remains yet to be done, and where materials so heterogeneous have been employed, that the system embraces in its various parts many things uncertain and hypothetical, and that will have to be modified or rejected with the

advance of knowledge. But no one would seem to be more sensible of this state of things than Professor Meynert himself. Of all the attempts thus far made to declare the inner architecture of the central nervous system, this of Meynert's is certainly the most noteworthy and comprehensive.

To what extent it is successful, will shortly be shown by the practical use that can be made of it in analysing and interpreting the problems of pathology that daily arise in clinical experience. But this test of utility is already being applied by Meynert, and is promised soon on his part by Dr. Huguenin, to whose practical work on diseases of the nervous system the monograph whose title stands at the head of this article is simply the 'anatomical introduction.' Hereafter we shall fully and plainly consider Meynert's views, in their practical as well as scientific relations.

In this notice of the outlines of his system, we have endeavoured to meet what has seemed to us a practical need on the part of many readers, who seem to have found it difficult to comprehend the somewhat novel and abstruse views of the great Vienna neurologist, which seem to us to have a high degree of practical importance when they are once understood.

ON A CASE OF HABITUAL ETHER INHALATION. BY DR. C. A. EWALD, FIRST ASSISTANT IN THE UNIVERSITY CLINIC, BERLIN.*

The case which I am about to bring before you must not be regarded as an observation of special scientific value, although we have endeavoured to make use of it in explaining some questions which lie before us; but rather as a kind of curiosity, an *unicum*, which, as far as my knowledge extends, has not hitherto been described, and is therefore worthy of being briefly communicated. There are, it is true, records in literature of a few cases in which large quantities of ether have been inhaled for a longer or shorter time; but in none of them was the quantity consumed so great as in our case, and in all of them the ether was used for therapeutic purposes. Moreover, these cases have not been sufficiently closely observed in their medical bearings.

About the middle of last month, a man, aged thirty-two, was admitted into the University Clinic, complaining of general *malaise*, weakness, loss of appetite, and muscular tremors. With the exception of slight enlargement of the liver, nothing wrong could be detected by examination; but his whole aspect was so indicative of misery, that he would have been put down as one of the wretchedly poor, were it not for the unusual contrast between his aspect and his distinctly formed speech, and for the fact that (as was at first thought) there was a remarkably strong smell of alcohol in his breath. The patient, however, explained that he did not smell of alcohol but of ether; and the peculiar sweetness and mildness of ether-vapour was then easily recognised, notwithstanding its strength. We learned that we had before us an unhappy individual, who, having begun some years ago to inhale ether, had become addicted to the habit to such a degree that he had fallen from a respectable station to his present condition,

* From the Medical Clinic of Medical Counsellor Frerichs. Read before the Berlin Medical Society, February 3, 1875. (*Berliner Klinische Wochenschrift*, March 15, 1875.)

and was extensively known in Berlin by the characteristic name of 'Ether-Fritz.'

In his earlier days, the patient was a temperate man, free from excesses of any kind. Occupied principally with philosophical and æsthetic studies, he seems to have had a greater inclination than was advisable to meditate on theologico-mystical subjects. In the meantime, he passed his school and university examinations with honour, and had, according to all expectation, a good prospect for the future. A work by Dieffenbach then fell into his hands, in which the action and use of ether in medicine were described, and the condition of narcosis was depicted in such glowing colours, that a fantastic mind might well expect something quite extraordinary from it. Among other things, it is said that the ether-narcosis is capable of facilitating to an extraordinary degree the creative power of the mind (*das geistige Schaffen*) and quickening its productivity; and so our patient thought that he had found in ether the means of fertilising his poetic fancy. In December, 1865, he first endeavoured to obtain the desired result by inhaling about two or two-and-a-half ounces of sulphuric ether, although he was quite well aware of the risk which he thereby ran. He lay alone on the sofa in his room, with a little bottle of ether, and a lighted candle near him; and inhaled the ether from a pocket-handkerchief. He immediately lost consciousness; and had a host of very lively illusions, principally consisting, it seems, of theologico-mystical conceptions, in which, however, as is the case in opium- and haschisch-smoking, there was a complete disregard of matter, time, and space. He believed that he had travelled through whole worlds and had lived for an infinity of time; and yet, when he awoke, his candle showed that he could scarcely have been narcotised a quarter of an hour. The ether-bottle was empty, although he did not remember taking it more than once in his hand. There was no vomiting; nor did he perceive any uncomfortable feelings either then or at any subsequent time after the inhalation of ether. He was thus not led to the use of ether by bodily pain; but he always used it for the sake of the narcosis itself, as a pure luxury, and thus his case differs from all that I have been able to find in German, English, and French literature. Unfortunately he was not satisfied with the result of this first attempt, for the stupefaction passed off at the moment when he seemed to have nearly reached the goal of his wishes. Naturally he repeated the experiment. The dream-world, however, into which he lulled himself, was not so splendid, not so rich in colours and images, as that of the first narcosis; and, however often he endeavoured to conjure it back by larger and larger doses, it would not reappear. The experiment soon became a habit, the occasionally made attempt an irresistible impulse, resembling that animal desire which constantly leads the drunkard to again seize the glass; and his original longing for the sublime and infinite became smothered in the desire for a stimulant, which at length assumed all the characters of an ordinary sensual passion. At first he only took the ether in his room; but soon he had no rest out of it. Holding a handkerchief saturated with ether before his mouth and nose, he staggered through the streets, running from one apothecary to another, and buying ether in small quantities, for his disordered circumstances no longer allowed him the means of procuring it in

sufficient doses to produce complete narcosis. At last he came to consume two or two-and-a-half pounds of ether in a day. A terror to his fellow-lodgers, who gave him notice to leave his dwelling on account of the smell of his breath, a dreaded and notorious visitor of the apothecaries, many of whom were obliged to close their doors against him, he became a homeless man, spending his nights in the open country, in new buildings, in dens, and in the custody of the police. No wonder that the results of such a life declared themselves in his physical condition, and that he applied to the Charité Hospital, in order to find there the means of renewing his reduced powers.

Divested of prolix philosophical comments, of numerous romantic episodes, and, I believe, of a good deal of colouring, this is an epitome of the patient's course of life, as he gave it in reply to my inquiries. It was now our part to test the truth of his assertions as far as possible. He is a middle-aged, lean man, with delicate muscles and skin; a small frequent pulse, moderate enlargement of the liver, frequent trembling of the limbs, slight injection of the conjunctivæ; but beyond this, his state seems in every way normal. There is nothing in his speech indicating that we have to deal with a man whose mind is impaired; his memory has not suffered; his thoughts are clear; his style flowing and even elegant; an unsteady and timid look, a quiet subdued behaviour, may fairly be attributed to the consciousness of his condition. Chronic indulgence in ether appears thus to lead, both externally and internally, to a condition resembling chronic alcoholism.

The nature of his hallucinations agrees completely with what I have found described in literature concerning ether and the long-known narcotics—opium, haschisch, betel-nut, coca, etc. That which is common to all of them is the removal from the real to the ideal; the individual differences depend on the sphere in which the individuals are accustomed to seek their ideal, on their power of imagination, and on their habits. The creation of phantasms is thus determined by the association of the individual consciousness; and in our patient this is sharply defined within its narrow limit. The character of his hallucinations was from the first, and has always remained, exclusively mystic, free from any erotic or other admixture, and has thus remained dependent on his prevailing disposition. As with other narcotics, so even more with ether, the disposition to hallucinative action appears to present individual differences; and a susceptibility of this kind, such as our patient has possessed in a more or less distinct form from the first day till now, may well be attributed in part to an alienated direction of his disposition or development—to a slight psychosis. This he has himself acknowledged.

With the tests of the truth of his statements, we endeavoured to combine our examination into several questions on the influence of ether on the vascular system and on secretion: and we concluded to subject him to a state of narcosis—which, indeed, he earnestly desired; for it was to be expected that he would require extraordinarily large doses, and we hoped that the physiological action of the ether would be especially distinct. Of chloroform it has long been known that, when inhaled in large doses, it produces mellituria (Reynoso, Sabbarth, etc.). A similar assertion is made regarding ether by Claude Bernard in his *Leçons sur les Substances*

toxiques; where he says that, after injecting ether into the portal vein or introducing it into the stomach of rabbits, he found sugar in the urine. Nothnagel observed some time ago, that the subcutaneous injection of chloroform was followed by the discharge of bile-pigment and blood in the urine. On account of the great similarity of action between ether and chloroform, it was *à priori* not improbable that ether would produce a similar condition. According to many authors, especially American, the number of respirations is increased, the heart's action is increased, the pulse becomes fuller and larger; and sphygmographic observations have been made by the American Morgan. I pass aside, as undisputed, the influence on the temperature and on the pupils. In order to produce complete narcosis, as indicated by loss of reflex irritability in the conjunctivæ, we gave, in thirty-three minutes, 280 cubic centimètres, or 207 grammes (about $7\frac{1}{3}$ ounces), of ether; administering it by means of an ordinary chloroform-inhaler, and preventing evaporation into the air as much as possible by applying cotton-wadding. But even with this enormous quantity we were able to produce only a momentary effect; for immediately on the cessation of the inhalation the patient came to himself, answered short questions correctly, walked steadily on the floor of the room, and, with the exception of some flightiness and confusion, appeared to be in quite the same state as before the inhalation. The narcosis presented nothing special, and resembled in all respects the sufficiently well-known phenomena presented by habitual drunkards during the stage of stupefaction. The patient, however, at first had an expression of extraordinary pleasure on his face, and inhaled the ether-vapour with real eagerness; he afterwards assured us that he had had a pleasant narcosis. Five minutes after commencing the inhalations, he was confused; in seven minutes, when 150 cubic centimètres (about four ounces) of ether had been used, the pupils became widely dilated, this state being apparently not preceded by contraction. The pulse, hitherto weak and low, became full and strong, and remained so as long as the narcosis continued, increasing in frequency at the same time from 72 to 80. The restlessness of the patient prevented a sphygmographic curve from being taken. The respirations were deep and increased from eighteen to twenty-five in a minute. After twenty-five minutes, violent hiccup set in, but ceased, as did also the dilatation of the pupils, as soon as the inhalation was discontinued. The urine passed immediately before and after the experiment was of a pale yellow colour, and quite clear; of specific gravity 1.009 and 1.006, without anything abnormal, and having no smell of ether; it was subjected to distillation without result.

It is obvious that only a certain value is to be attributed to this negative result. Even if we must set down a part of the ether to the account of habit (and a certain amount of tolerance on the part of the organism is doubtless to be attributed to this), still the amount greatly exceeds the highest known to have been taken in other cases—eighty or ninety grammes. The patient was indeed in the habit of taking enormous quantities in the course of the day; but a large portion must have generally escaped into the air, and, as it seems, it was but very rarely that he was completely narcotised. We convinced ourselves of this by allowing him to etherise himself. He placed his handkerchief over his mouth

and nose, laying a pencil and a piece of paper near him to note down any of his thoughts, and from time to time poured out fresh ether, so that he pretty soon fell into a state of intoxication, during which he talked extravagant nonsense, danced about the room, laughed, and appeared to be very much pleased; but his condition was far removed from narcosis in its ordinary sense. After he had used about 130 grammes of ether in the course of an hour and a half, we made him desist; otherwise he would have probably passed the whole day in the same manner. It was, however, not to be expected that this slow and often interrupted kind of absorption should exert any distinct influence on tissue-change. The pulse, as we now ascertained by the sphygmograph, was not once changed; nor was there any alteration in the urine. I must, therefore, regard the assertions regarding the presence of sugar, bile-pigment, and blood in the urine, at least as far as the observations before us go, as not applicable to man.* The air expired by the patient, at the end of eight days after the last experiment, still had a strong smell of ether.

The patient was treated by restoratives and cold baths. With these we combined absolutely large but probably relatively small doses of extract of cannabis Indica, so that his nerves might not be too abruptly deprived of their accustomed stimulus. It was interesting to observe that the susceptibility to this drug was not lost. On the first day we gave too large a dose, and towards the evening the patient had phantasms in the form of panoramic buildings, landscapes with temples, waterfalls, etc.; from these he could at any moment withdraw himself, and have again before his eyes the ward of the Charité Hospital. This agrees perfectly with other observations on haschisch-smoking. We at once reduced the dose, without allowing further toxic symptoms to be produced.

Such are the experiments which we considered ourselves justified in making on the patient. Although there is but little prospect that, when at liberty, he will throw off his ordinary disgrace, we thought that we ought not to give further countenance to his habit. The gain is not great; and when we look closely into the matter, the case is only one of those which fall under our notice by hundreds and thousands in other shapes; illustrating the power of emotion, and of the instinctive longing of human nature to raise it above the sameness of every day life by the use of luxuries of some kind. But the whole world smokes tobacco; 400 millions of men stupefy themselves with opium; 300 millions eat and smoke haschisch; while our patient is the first in whose hands the anæsthetic power of ether has been misused to gratify a passion for intoxication.

It is, if you will, a new and probably unique form of drink-madness; but the extraordinary character of the case leads me to believe that it may not be thought unworthy of this brief exposition.

A. HENRY, M.D.

* In five rabbits, which I poisoned with increasing doses of ether (six to sixteen cubic centimètres, partly injected under the skin, partly given by the mouth), the bladder contained in each case only a few drops of urine, in which no sugar could be found. In one of the animals, a few red blood-corpuscles were found in the urine. The animals died from an hour to an hour and a half after the poisoning.

ANATOMY AND PHYSIOLOGY.

RANVIER ON THE PREPARATION OF BONY TISSUE WITH BLUE ANILINE DYE INSOLUBLE IN WATER AND SOLUBLE IN ALCOHOL.—This method, described by M. Ranvier in the *Archives de Physiologie*, February, 1875, is alleged to possess certain advantages over the one usually employed in the examination of bone, namely, of mounting dry sections in Canada balsam. By the use of the following means, the structure of the object is far more perfectly shown.

A portion of the shaft of a long bone is procured, and immediately on removal from the body is plunged into water. It is allowed to macerate in this for the space of a year; the water in the mean time being repeatedly changed. At the end of that time the bone will be found to have become as white as ivory, and quite free from any adhering tissue. The object of immediately plunging the bone in water is to prevent the infiltration of the canals and substance of the bone with fat.

When the bone is thoroughly macerated, sections of it are made with a saw. These sections are ground down on pumice-stone, and finally polished on a harder material. In order to remove the powdered fragments of bone which have been ground off, from the canals and lacunæ on the surface, it is sufficient to scrape the section with a scalpel. It is then placed in a warm solution of the aniline, and allowed to remain there for two hours, and afterwards dried on a water-bath.

The section is next rubbed on a hone, moistened with a 2 per cent. solution of common salt. It is then washed in this solution, and permanently mounted in a mixture of equal parts of the solution of salt and glycerine.

In objects prepared in the above manner three important facts, not previously noticed, may be observed.

The first is the existence of lacunæ or corpuscles, consisting of a simple slit, not much larger than a canaliculus. The fact of their being lacunæ is proved by the relation in which they stand to the canaliculi, which is precisely the same as that of other lacunæ. The name given to these fine atrophied corpuscles or lacunæ is *confluents lacunaires*. They are lacunæ either partially or completely atrophied. This observation bears out the theory of the disappearance of the lacunæ with age. But this disappearance is not due to the lacunæ being filled up with fresh bone, but rather to a process of atrophy.

The second interesting fact rendered clear by this method is, that the canaliculi which are given off from the outer sides of the external lacunæ of each Haversian system proceed for a short distance as though they were going to inosculate with a neighbouring system. They then turn on themselves, and inosculate with other canals belonging to their own system. These are called *canalicules récurrents*. From this fact we may conclude that each Haversian system forms a complete structure by itself, and represents the elementary bone.

The third fact relates to the structure which intervenes between the Haversian system. In transverse section there may be observed, in these islets of bone, certain small circles which represent the fibres of Sharpey divided transversely. These circles are only

to be seen in the intermediate structure, never in the Haversian system. This fact proves that the substance in these localities is developed from the periosteum. The relation which the corpuscles and canaliculi bear to the fibres of Sharpey may be briefly stated as follows. The corpuscles are placed in the angles formed by the intersection of these fibres. The canaliculi surround the fibres, but do not pass through them. This last fact, taken into consideration with that of the recurrent canaliculi of the Haversian system, proves that the canaliculi are spaces left in the substance of the bone at the time of its development, and not fissures made during the preparation of the section.

[The above paper is accompanied with a plate which demonstrates very fairly the facts pointed out by the author.—*Rep.*]

BENEDIKT ON THE PHYSIOLOGY AND PATHOLOGY OF THE PYRAMIDS OF THE MEDULLA OBLONGATA.—In a paper originally published in the *Wiener Medizinische Presse*, Dr. Benedikt seeks to prove that the commonly received opinions as to the functions of the pyramids are wrong. He commences by stating that the pathological teaching of the present time asserts that the pyramids are the conductors of the excito-motor impulses in a centrifugal direction, and of sensation in a centripetal direction; but that the real fact is, that they are neither motor nor sensitive in the sense intended by Bell. He proceeds to state that anatomically the pyramids may be divided into bundles of fibres, which are continuations of the lateral and posterior columns of the cord. Fifteen years' clinical experience, more particularly of the facts presented by *tabes dorsalis*, have lead him to the conclusion, contrary to that of most physiologists and pathologists, that the bundle which is the continuation of the posterior cord consists of fibres of a regulating and co-ordinating motor nerve-system, and that Bell's doctrine of their connection with the central nerve-system is in opposition to pathological truth. The physiological conclusion, also, that the external bundle of the pyramids is sensory, because of its connection with the posterior column of the cord, is wrong in principle, and involves a *petitio principii*, as it is necessary first to prove the sensory property of the posterior cord itself. Neither the external nor the internal bundle forms any direct continuation with the spinal cord.

Experimental physiology is thus, with one exception, in the dark as to the nature of the pyramids. It says that the negative results obtained by section of these parts renders their nature enigmatical. An experiment by Harless, confirmed by Cyon, is the only one that bears out the author's views. The correctness of the conclusion deduced from this is, however, disputed. Pathology, according to the author, if properly viewed, presents a more satisfactory solution of the question. Careful observation of disease has convinced him that, when these parts are affected, there is a certain innervation of the motor power, more particularly of the upper limbs, a disagreement between antagonistic groups of muscles, the result of which is an inaccuracy in obeying the ordinary motor impulses of the will. If, however, the will be more powerfully exerted, this inaccuracy is overcome.

W. KESTEVEN, JUN.

BLANCHE ON EXPERIMENTAL RESEARCHES ON PROTOXIDE OF NITROGEN.—Dr. Tony Blanche (in *Thèses de Paris*, 1874), gives as the result of his very

complete and extremely interesting experiments on the mode in which protoxide of nitrogen acts, that of all experiments made on protoxide of nitrogen one great fact results; it is that asphyxia supervenes in persons submitted to the inhalations of this gas, an asphyxia demonstrated by indisputable signs. In all the experiments reported these symptoms have been remarked, and Drs. Jolyet, Tony Blanche, Charcot, Blot, Laborde, and Dumontpallier have all testified to having seen the purplish colour of the face, the slackening of the respiration, etc., which M. Charcot characterises as an extremely serious condition, bringing to mind certain phenomena of the death-struggle. M. Magitot entirely shares the opinion expressed by MM. Charcot and Blot on the subject of the surgical employment of this gas. The number of known deaths increases daily, and in all which have been ever so little studied, the accident has been the result of asphyxia. Some necropsies have been made, and have plainly demonstrated this mechanical action. It has been alleged that the bad quality of the gas used for the experiment explains the asphyxia; but such is not the case, for M. Pictet had observed these alarming symptoms even in experiments carried on at the house of the inventor of protoxide of nitrogen. Besides, if the preparation of the gas present difficulties of the most delicate kind, which is certainly the fact, that only constitutes an additional danger in addition to those which are already sufficient to proscribe inhalations of protoxide of nitrogen. From his own personal experiences Dr. Tony Blanche comes to the conclusion that chemically pure protoxide of nitrogen cannot maintain the respiration of animals any more than that of vegetables. Combustion, in which respiration consists, is not sufficiently powerful to decompose this gas. Breathed in a pure state by animals, the protoxide of nitrogen is then an asphyxiating gas, which brings on death by producing all the usual signs of asphyxia by strangulation or by the respiration of inert gases (hydrogen and nitrogen). If protoxide of nitrogen inhaled in a pure state produces anæsthesia, it is by acting as an asphyxiant in consequence of the want of oxygen in the blood. Insensibility only shows itself when there are only two and three per cent. of oxygen in the arterial blood; the blood is then very black. Animals, on the contrary, can live if they breathe artificial atmospheres of protoxide of nitrogen and oxygen, in the proportions of the aerial gases; protoxide of nitrogen replacing the nitrogen without showing disturbances of sensibility. Protoxide of nitrogen appears, however, to leave an action not clearly defined on the brain, somewhat analogous to that determined by the diminution of oxygen, and not bringing on loss of consciousness. He is also of opinion that protoxide of nitrogen, being an irrepressible gas of which the preparation offers certain difficulties, and which only produces anæsthesia as a consequence of the asphyxia it produces, and its use having caused death in several instances, its employment ought to be, if not completely abolished, at least greatly restricted, in medical practice.

JAFFE AND DONCHIN ON THE PHYSIOLOGICAL EFFECTS OF SALTS OF DINITROBENZOLE.—At a meeting of the Königsberg (Prussian) Verein für Wissenschaftliche Heilkunde, on February 23, 1874 [see report in the *Berliner Klinische Wochenschrift*, for January 11, 1875], Herr Jaffe communicated the results of some experiments made by him in conjunc-

tion with a student named Donchin, on the physiological effects of salts of dinitrobenzole ($C_6H_4(NO_2)_2$). The test employed was a modification of a very sensitive one for carbolic acid lately proposed by Jacquemin; and they had demonstrated that after the ingestion of dinitrobenzole, whether by mouth, or subcutaneously, even in very small doses, carbolic acid can always be obtained from the blood and urine. It is not quite clear that it exists as such in these fluids, as it may possibly be formed during distillation out of undecomposed dinitrobenzole. These experimenters also noticed in rabbits thus poisoned that the muscular tissue of the heart retained its irritability many hours after death, just as Cunze has shown to occur in poisoning by arsenious and arsenic acids. Only the auricles, particularly the right, continued their spontaneous movements as long as nine or ten hours after death. These phenomena were only observed in cases where the animals died soon after taking the poison, from asphyxia. In protracted cases the heart became gradually paralysed, and after death was found immediately both motionless and devoid of irritability. If Cunze's explanation be adopted, that these phenomena are to be attributed to the power of preventing fermentation and putrefaction possessed by arsenical acids, the same phenomena in dinitrobenzole poisoning should probably be attributed to carbolic acid. As a matter of fact, it was so in poisoning by pure carbolic acid, and the contractions of the right auricle continued more than ten hours after death. All antiseptic and antizymotic substances apparently act in the same manner; and Herr Jaffe had proved this most remarkably in the case of strychnine.

W. BATHURST WOODMAN, M.D.

ORD ON THE NATURAL HISTORY OF THE URATES.—Dr. Ord (Transactions of the Royal Microscopical Society, in the *Monthly Microscopical Journal*, March, 1875) has studied experimentally the forms assumed by urate of soda and urate of ammonia, when deposited from water alone or in the presence of other substances, as gelatin, albumen, chloride of sodium, or other salts and acids. The general result is, that two forms at least must be added to the three already known, viz., crystalline, spherical, and amorphous. The five forms thus recognised may be arranged in the following order, according to their several degrees of departure from what the author calls 'the colloidal or quasi-living state' to the 'crystalline or not-living state': 1. Gelatinous colloid; 2. Molecular urate; 3. Spherules of the first kind, soft, and tending after a time to crystallise; 4. Needles; 5. Spheroids of second kind, composed, as the author believes, of matter originally crystalline, but subdued by the colloid medium to a colloid form. The spherules (3) are large and soft, and break up after a time into needles; they are formed under two conditions, either in acid urates, or the combinations of hot saturated solutions of urates with chlorides or phosphates of alkalis. The spheroids of the second kind (5) are dense and compact; they are formed by acid urate in gelatin.

J. F. PAYNE, M.B.

THE annual dinner of the Chairman and Committee of Management of King's College Hospital will take place on Wednesday the 14th inst. His Royal Highness the Duke of Cambridge, President of the Institution, will take the chair. The dinner will be served at the college at a quarter to seven o'clock.

MEDICINE.

MANN ON NASAL CATARRH.—Dr. Edward C. Mann has contributed a valuable paper on the pathology and treatment of nasal catarrh to the October number of the *New York Medical Journal*. Commencing with an excellent account of the normal anatomy of the Schneiderian mucous membrane, he proceeds to describe the changes it undergoes in acute and chronic catarrhal inflammation.

‘At the outset of an attack of acute nasal catarrh, the capillary vessels of the nasal mucous membrane are distended with blood, the tissues are infiltrated, and from the mucous membrane, swollen by congestion and œdema, is discharged a thin, colourless saline secretion. After the primary swelling and congestion have subsided, this secretion becomes thickened from the addition of young cells. If the disease run into the chronic form, we shall find the nasal mucous membrane considerably thickened, especially the mucous membrane covering the turbinated bones. The swellings of the nasal mucous membrane do not have their seat in the mucosa, but are œdematous infiltrations of the submucous connective tissue. The swelling is dependent upon the amount of hyperæmia, so far as depends upon the increase of volume of the vessels, and upon a more abundant saturation of the mucous membrane with serum. After this condition, which characterises acute catarrh, the mucous membrane may return completely to its normal condition, but it is liable, upon any slight irritation, to again take on catarrhal inflammation; and such relapses are much more difficult to treat than was the primary disease. Each relapse increases the proliferation of cells in the submucous connective tissue. The epithelium and mucous glands gradually enlarge, and the mucous membrane passes into an hypertrophied condition.

‘In chronic nasal catarrh we find, in many instances, catarrhal ulcers, superficial as a rule, but which in scrofulous and cachectic patients may penetrate more deeply, destroying the perichondrium and periosteum, and giving rise to caries and necrosis of the cartilages and bones of the nose. In these cases, the secretion from the nasal passages is extremely offensive, requiring the use of deodorising solutions of chloride of lime, or permanganate of potassa, which may be used with the posterior nasal syringe or nasal douche.’

In some cases the mucous membrane is relaxed, in others it assumes the condition of ‘mucoid polypous outgrowths.’

The symptoms of acute and chronic nasal catarrh are next given, but, as these are well known, we need not dwell upon them. Dr. Mann says, ‘By means of rhinoscopic examination we are enabled, much more accurately than formerly, to determine the seat and progress of nasal catarrh, and to make local application to the mucous membrane covering the turbinated bones and septum, which are the parts especially liable to take on ulceration; and it is here also that we find the greatest thickening and hypertrophy of the mucous membrane, resulting sometimes in the production of mucoid polypi. These polypi owe their production to a circumscribed hypertrophy of the mucous membrane, which is especially concentrated upon the glands. The principal mass of the tumour is formed by hypertrophic

glands, and is attached to the mucous membrane by a more or less distinct pedicle.’

The most important part of the paper is, however, that devoted to treatment. This should be partly constitutional and partly local. Iron, quinine, and cod-liver oil, combined with iodine in scrofulous cases, are the remedies suggested for improving the general health.

Before resorting to the application of local remedies, Dr. Mann recommends the nasal cavities to be thoroughly cleansed, anteriorly and posteriorly, with Thudicum’s nasal douche, or the posterior nasal syringe, and a warm saline solution, containing sixty grains of common salt to the pint of water. A solution of nitrate of silver in glycerine (gr. sixty to one oz.) should next be applied thoroughly to the entire surface of the nasal cavity, to diminish the congestion and thickening of the mucous membrane. This application is recommended to be followed by the propulsion of the vapour of iodine into the nasal cavities anteriorly, by means of an instrument which is made of ‘hard India-rubber, having a cavity filled with sponge which is medicated with the tincture of iodine. Upon one end of this hard rubber apparatus is attached a nasal tube fitting into the nostril, while to the other extremity is attached a soft rubber bulb with a flexible tube. By compressing the bulb, atmospheric air, or steam if desired, is forced through the hard rubber apparatus containing the sponge saturated with iodine, and diffuses the vapour of iodine throughout the entire extent of the nasal cavities, exerting a powerful alterative and curative effect upon the mucous membrane.’

The application may be continued for a quarter of an hour at a time, and repeated every other day.

Besides the above, Dr. Mann prescribes a snuff, composed of equal parts of finely pulverised camphor and powdered white sugar, to be used *ad libitum*, and he says ‘patients are unanimous in their expression of relief subsequent to its use.’ The other local measures recommended are injections (ʒij to water ʒij), and sprays of sulphate of zinc and copper.

When there is ulceration of the mucous membrane and caries of the bones of the nose, a solution of iodine and iodide of potassium in glycerine (℞ iodinii gr. ij, potassii iodidi gr. xij, glycerini ʒij.) applied over the affected parts, is of great service. Polypous outgrowths should be removed by twisting them off by forceps, or encircling them with a wire snare and then cutting them off by drawing the loop tight, after which the remaining portion may be cauterised with nitrate of silver.

Dr. Mann next cites three very interesting cases of chronic nasal catarrh cured by the measures he recommends, and concludes his paper by the following results of his experience. ‘If cases can be seen at the outset, or before thickening of the mucous membrane has taken place, they can be easily cured, while cases of long standing invariably require protracted treatment for the accomplishment of a thorough cure.’

[Physicians, who have had obstinate cases of œzœna under their care, gladly welcome any suggestions which are likely to relieve their patients of this most cruel malady. The reporter has recently had under his care two obstinate cases of this disease, and can fully bear out Dr. Mann’s recommendations as to the importance of constitutional treatment. The only local applications which have been of service, after thoroughly cleansing the nasal cavities, have been solution of permanganate of potash and

citrine ointment diluted with olive-oil. The mercurial and other snuffs recommended by Trousseau were useless. In one of the reporter's cases, the fetor was much increased at each catamenial period.—*Rep.* J. B. BRADBURY, M.D., Cambridge.

GUEDES ON A CASE OF FLOATING KIDNEY.—At a meeting of the Lisbon Medical Society, on February 13 (*Correio Medico de Lisboa*, February 22), Senhor Ramiro Guedes related a case of floating kidney. It occurred in an unmarried lady, aged forty, a schoolmistress. She first came under notice in May, 1874, and stated that, a little more than a month previously, she observed one morning an abnormal prominence in the left side of the abdomen, and at the same time began to feel severe pain in the lumbar region. She had been nursing her mother, who was suffering (it was said) from uterine cancer, and was a very heavy woman; and she attributed the symptoms of which she complained to the exertion used in raising her mother and changing her position in bed.

About a fortnight before Dr. Guedes saw her, the patient's abdomen became considerably enlarged and tympanic; she had constipation, fever, and severe pain in the abdomen, and the tumour became indistinct. After the use of a laxative and fomentations to the abdomen the symptoms subsided, and the tumour could be again felt. On examination, Dr. Guedes ascertained the tumour to be a floating kidney, on the left side. He advised the patient to apply a bandage round the abdomen, to apply a liniment of oil of hyoscyamus and chloroform to relieve the tenderness, and, as she was much debilitated, to take pills containing three-fourths of a grain each of sulphate of quinine and lactate of iron, and a grain and a half of extract of gentian.

The case was also examined, at the invitation of Dr. Guedes, by Dr. Flores; who considered that, in addition to its displacement, the kidney was affected with cancer. He based this opinion on the colour of the patient's skin, which was indicative of cancerous cachexia, and on the circumstance that (as was reported) her mother had died of cancer of the uterus. Dr. Guedes, however, in the absence of any further indications of renal cancer, held to his belief that the case was simply one of floating kidney.

The patient passed from under the observation of Dr. Guedes; but he learned that she died sometime afterwards, having suffered from lancinating pains in the abdomen, diarrhoea, and hæmorrhage—symptoms, he believed, of peritonitis produced by the irritant action of the displaced kidney, which acted as a foreign body in the peritoneum.

A. HENRY, M.D.

SPECK ON DEATH FROM A RATHER HIGH TEMPERATURE.—C. Speck publishes a case, in Eulenberg's *Vierteljahrsschrift für gerichtliche Medizin und öffentl. Sanitätswesen*, vol. xxi., quoted in *Centralblatt für die Medicinischen Wissenschaften*, Feb. 27, 1875, of death which he attributes to a high temperature. A girl aged seventeen, who had suffered for eight years from contractions of all her joints, was enveloped, as a remedial measure, in the skin of a sheep just killed, then surrounded with fresh-baked hot bread, and a covering thrown over all. She complained after an hour of feeling uncomfortable, and of pain, then sank into sleep, then had difficulty of breathing, and perspired a great deal; lastly, became pale, and died about three

hours from the beginning of the 'cure.' The most marked feature of the necropsy was advanced decomposition, although the surroundings were not favourable to this. The finest vessels in the pia mater were injected, whilst the larger were almost empty of blood, but contained air [*sic*]. The heart and large vessels were almost bloodless; the pericardium contained frothy fluid. The walls of the heart were pulpy, and studded with punctiform ecchymoses. The medico-legal report was to the effect that, in the absence of any other cause of death, the advanced decomposition pointed to decomposition of the blood, and that death was probably due to the so-called 'cure.' Reference was made to the investigations of Bernard and Ackermann, showing the injurious effects of temperatures equalling or exceeding the normal temperature of the body. Speck satisfied himself that bread exposed to the air in a room at the temperature of 16° or 17° (60° to 62° Fahr.) had, after two hours, a temperature of 45° (113° Fahr.) in the interior. [The reporter thinks it far more reasonable to attribute this death to the carbonic acid, etc., given off from the bread, especially as he knows of a somewhat similar case, which occurred in the country some years ago, when death, with all the signs of suffocation, followed from a similar procedure advised by a quack. It is also well known that accidents of this kind used to occur to journeymen-bakers some years ago. The empty condition of the heart and great vessels was, no doubt, due partly to the youth of the victim and partly to decomposition.—*Rep.*]

DISEASES OF CHILDREN.

HEINZEL ON OPHTHALMOSCOPIC EXAMINATION IN CEREBRAL DISEASE IN CHILDREN.—In the *Jahrbuch für Kinderheilkunde*, Dr. L. Heinzel contributes a series of observations on the diagnostic value of ophthalmoscopic examination in cases of intracranial disease in children. His conclusions are based upon a tabulated series of sixty-three cases; and though he confesses that he is unable to bring forward any general principle of positive value, yet he believes that they furnish negative evidence of some importance.

In forty-seven of the sixty-three cases of intracranial disease, a morbid condition of the fundus oculi was ascertained by the ophthalmoscope; in sixteen cases there was no optic disease. Of the forty-seven, eighteen were cases of neuro-retinitis;

thirteen of neuro-retinitis and papillary engorgement; four of congestion of the optic nerve; four of optic neuritis and papillary engorgement; two of atrophy of the optic nerve (consecutive); and six of atrophy of the optic nerve (genuine).

In thirty-one cases of tubercular meningitis of the base, it was observed that neuro-retinitis occurred in fifteen, neuro-retinitis with papillary engorgement in five, congestion of the optic nerve in four, commencing atrophy in two, genuine atrophy in one, and the condition was normal in four.

In ten cases of acute tuberculosis, where other organs were affected with tubercle, neuro-retinitis occurred in three, optic neuritis with papillary engorgement in one, atrophy of the optic nerve in three, and normal condition in three.

In fourteen cases of tumours of the brain, neuro-retinitis occurred in five, neuro-retinitis and subsequent atrophy in two, genuine atrophy in four, and normal condition in three.

In two cases of oedema of the brain the optic nerves were congested. The condition of the ophthalmic nerve was normal in two cases of oedema of the meninges, with chronic hydrocephalus; in one of oedema of the meninges and phthisis pulmonalis; in one of hyperæmia of the meninges; in one of sclerosis cerebri; in one of cerebro-spinal meningitis, and in one of hydro-rhachis.

STEFFEN ON STRIPED PNEUMONIA.—In the *Fahrbuch für Kinderheilkunde und Physikal Erziehung*, February, Dr. Steffen describes, under the term 'striped pneumonia,' a pathological condition characterised by inflamed condensation of the lung-tissue in the form of stripes. These extend from the spine towards the costal angles, and may traverse only one lobe, or may take such a course as to affect more than one. The various ages at which this form of inflammation occurs are exhibited in a tabulated statement, and allow the conclusion that it is most frequent between the fourth and twelfth month, and diminishes progressively up to the ninth year. These conclusions are founded upon an analysis of ninety-seven cases, of which fifty-four were boys and forty-three girls. It was met with most frequently on both sides of the chest, though, like other forms of pneumonia, it may be more marked on one side than on the other. It is not associated with pleurisy, and thus differs from acute pneumonia in adults. Pathologically, the disease consists of infiltration of lung-tissue with blood, at the same time that there is desquamation of the pulmonary epithelium. It occurs with emphysema and passive congestion, though the affected portions of the lung may be distinguished clearly by their colour from those in the latter condition. Among other complications, peribronchitis, pneumonia, and oedema occur very frequently. Constitutional predisposition and malnutrition are the most common causes which tend to this form of pulmonary disease.

LARYNGEAL GROWTHS IN CHILDREN.—In the *Fahrbuch für Kinderheilkunde* (February), Dr. Klemm makes some general remarks on laryngoscopy, and relates two cases of growths in the larynx in young children.

The first (girl, aged six) terminated fatally after tracheotomy. The right true vocal cord was entirely converted into an irregular papilliform excrescence, the left almost entirely, the masses being separated to some extent from one another. Their microscopical

character was not determined. The disease was acute; fourteen weeks having elapsed between the first symptoms of laryngeal disturbance and the time of the operation.

In the second case (girl, aged two and a half) the disease, without known cause, had continued since the age of three months, and gave rise to no severe symptoms. A small red polypus, of the size of a pea, was observed near the posterior angle between the cords. No treatment was adopted.

ROBERT J. LEE, M.D.

SURGERY.

FALK AND VON LANGENBECK ON SHOCK.—Dr. Falk, at a recent meeting of the Berlin Medical Society, reported in the *Berliner Klinische Wochenschrift*, no. 8, 1875, referred to cases of wounds of the abdomen causing speedy death. In these cases all the phenomena were presented of the condition described by John Hunter and English surgeons particularly as shock. In death from shock, there is no palpable lesion to account for the fatal result; and no direct injury of any central organ can be demonstrated. The blood supplying the ganglionic apparatus of the heart and brain is not impaired in quality. Collapse and death occur quite independently of organic injury of any abdominal viscus. Dr. Falk, recognising failure of the heart's action as the most prominent symptom of shock, holds that much light may be thrown on this subject by consideration of some recent physiological experiments. In Goltz's well known experiment, the so-called *Klopfversuch*, a blow on the abdomen of a frog, will cause a sudden arrest of the cardiac movements in consequence of reflex irritation of the inhibitory fibres of the vagus. In a more recent experiment made by Fischer, it was found that frequently repeated blows on the abdomen of an animal will also impair the cardiac movements; and, at the same time, produce an arrest of the circulation in the abdominal viscera, in consequence of which less material is supplied for keeping up the contractility of the heart, which organ exhausts itself in frequent fruitless contractions. Similar processes occurring in the human body after injury to the abdomen might serve, according to Dr. Falk, to account for fatal shock; but he holds that they never constitute the sole cause, but are always associated with loss of blood or a morbid condition, either inherited or acquired, of the heart and large vessels. Dr. Falk believes that cases of fatal shock during the performance of a severe operation have occurred less frequently since the introduction of anæsthesia, and he alludes to the fact that Goltz's experiment fails when performed on a frog deeply under the influence of chloroform. It has been pointed out, however, by physiologists at Vienna, that irritation of the nasal terminations of the trigeminus by the inhalation of chloroform may cause arrest of the heart's action and of respiration.

In the course of some remarks on Dr. Falk's paper, Herr von Langenbeck stated that he had long excluded the term shock from his surgical nomenclature, because it represented to him no clear idea, and had been applied to many very different conditions. In recent times, the term had been used to account for death occurring during operations, when the fatal result could not be otherwise accounted for

than by hæmorrhage, and, in cases of operation on the jaws and mouth, by suffocation. Shock could not rightly be regarded as a cause of death after resection of the hip. According to the reports of Otis, the deaths from supposed shock occur after primary resection performed immediately, or in the first twenty-four hours after severe injury. Death seldom, if ever, occurs from shock in the intermediary or infiltration period. In instances of this kind, according to the views of Von Langenbeck, death is due, not to shock, but to loss of blood. Von Langenbeck stated that he had never known death to occur in cases of wound of the abdomen, until after such an interval as would permit the development of peritonitis.

WEIGAND ON GANGRENE OF THE PENIS AND SCROTUM.—Dr. Weigand, of Colmar, reports in the *Berliner Klinische Wochenschrift*, no. 10, 1875, two cases of gangrene of the male genitals. In the first case, extensive gangrene of the penis and scrotum, with much constitutional disturbance, occurred three days after the commencement of a paraphimosis in a soldier, whose prepuce had previously been in a normal condition and could be readily drawn back over the glans penis. The treatment consisted in the administration of quinine and wine, and in the application to the gangrenous parts of charcoal. After exposure of both testicles, and destruction of a greater part of the skin of the penis, healthy granulation was established, and the patient made a good recovery. In the second case, the integument of the left side of the scrotum became gangrenous, after the application of a compressing bandage for the treatment of gonorrhœal epididymitis. In this case, although there was much destruction of soft parts, the general health remained good, and the temperature was not elevated. In this, as in the preceding case, the seat of the disease was freely dusted with charcoal. These two cases are supposed by Dr. Weigand to present several points of interest. In the first place, they occurred at the same time, and this coincidence suggested the idea of contagion, which, however, was soon rejected by Dr. Weigand, on recognising the facts that the local symptoms were quite different from those of hospital gangrene, and that in the same ward with these two patients were several others suffering from open buboes and recent chancrous ulcers, who remained unaffected. In the first patient, the prepuce had previously been in a normal condition, as there had not been a congenital phimosis; here, therefore, we have an exception to a rule laid down by Bardeleben and other surgeons, that paraphimosis occurs only in those subjects who have drawn from over the glans penis an abnormally long prepuce, with a contracted orifice. Dr. Weigand has observed several exceptions of this kind, and states that in these cases the paraphimosis is due to inflammatory swelling of the mucous membrane about the corona glandis, excited by soft chancres, balanitis, or increased glandular secretion; the extension of this swelling to the prepuce rendering it difficult or impossible for the patient to cover the glans again. In Dr. Weigand's case, the paraphimosis was reduced without difficulty and with but little force; but still gangrene resulted, probably because the compression of the integument and its vessels had been kept up too long, and probably because also the constricting ring had not been sufficiently relaxed. Dr. Weigand now lays it down as a rule always to incise this ring in cases where

paraphimosis is not very recent. In the second case, the gangrene of the scrotum is attributed to compression of the anterior scrotal artery of the affected side by the compressing bandage used for the treatment of swelled testicle. One cannot, Dr. Weigand holds, account in any other way for the fact that only the compressed portion of the scrotal integument became gangrenous. In conclusion, Dr. Weigand recommends strongly the old and, as he thinks, obsolete practice of applying powdered charcoal to ill-smelling gangrenous surfaces.

W. JOHNSON SMITH.

VOLKMANN ON ANTISEPTIC OSTEOTOMY.—Mr. Lister publishes, in the *Edinburgh Medical Journal* for March, a communication from Professor Volkmann, of Halle, in which he relates with great satisfaction the very favourable results which he has obtained from the antiseptic treatment of wounds. He describes his hospital as being old, with bad sanitary arrangements, and always overcrowded, yet since the introduction of Mr. Lister's method two years ago sixty major amputations have been performed without one case of pyæmia; thirty-one compound fractures, many of them very bad cases, have been admitted during the same time and have all been successfully treated; among these were two cases of compound comminuted fracture of the patella, both of whom recovered with movable joints. As a consequence of this success, Dr. Volkmann has been able to advise with more confidence the performance of operations of expediency, 'the justification of which,' he says, 'undoubtedly depends entirely on the possibility of guaranteeing a successful termination.' For instance, during last year he performed osteotomy thirteen times for the relief of faulty ankylosis of the hip and knee joints, and in every case the operation was perfectly successful. In none of them did the least redness or swelling of the soft parts occur, and only in three cases was there the smallest attempt at suppuration. In most instances he simply cuts through the femur or tibia, or both, with a chisel, but if the amount of flexion be extreme, a wedge-shaped piece of bone must be removed. He points out that in many cases, of stiff knee more especially, simple extension of the limb is either impossible, owing to former bony ankylosis, or is inexpedient owing to deformity of the condyles of the femur or to subluxation of the head of the tibia; in these latter cases forcible extension is very apt to leave a weak useless limb, and a recurrence of the contraction often happens. Most of the patients thus operated on by osteotomy would therefore only a few years ago have been subjected to amputation below the knee; this simple operation now restores to them a sound and useful limb, and they are able to walk well, at all events with the aid of a thick-soled boot.

OBSTETRICS AND GYNÆCOLOGY.

KEITH ON SUPPURATING OVARIAN CYSTS.—Dr. Thomas Keith (*Edinburgh Medical Journal*, Feb., 1875) gives the following cases, as proving that ovariectomy should be the rule in cases of acute suppuration in ovarian cysts, or when typhoid symptoms come on after tapping. He briefly sketches a case which was under his care ten years ago, the patient arriving exhausted with a long journey, with vomiting, diarrhoea, oedematous limbs, albuminous urine, and profuse foetid discharge from an opening near the umbilicus. In those days, ovariectomy was not thought of in such a case, but the miserable lingering death made a strong impression upon Dr. Keith.

Soon afterwards, in 1864, another case came with a very large tumour, the patient suffering much from jolting in a coach. She was tapped, but without relief. Abdominal distension and typhoid symptoms came on; and fearing a repetition of the slow death he had seen, he performed an operation during the semi-delirium of septic fever. The peritoneum was almost black, the intestines highly inflamed, the base of the cyst sloughing and gangrenous. After an operation lasting two hours, the patient was placed in bed, cold, vomiting, and nearly pulseless; but the delirium passed off, perspiration came on, and she recovered without a drawback.

This case acted as a landmark; and in twelve cases which Dr. Keith has since had (ten of acute suppuration and two of chronic) ovariectomy has been tried in all but one, and was only put off in this case on account of the wretched home and surroundings of the patient, who was seen for the first time three days after her fourth confinement. Immediate tapping was necessary to relieve urgent dyspnoea, and six gallons of fluid were removed. It was found impossible to move her into better quarters for operation; and in three weeks she was again tapped, and the cyst-contents were intensely putrid; the cannula became choked, and a larger opening was made, and the cyst cleared out with the fingers. The cyst was fortunately single; and, after long and exhausting suppuration, during which she was solely supported by milk and butter-milk without stimulants, she recovered, and has since borne two children.

Of ten more or less acute cases operated on, eight recovered, and the two chronic cases got well easily.

Dr. Keith gives details of seven cases occurring in the course of his second hundred ovariectomies, and not before published.

[The following are brief abstracts of these remarkable results, which we should advise all to read for themselves in the original paper.—*Rep.*]

Case 1.—*Recovery.* Mrs. M., aged thirty-five. The tumour was detected in 1869; Dr. Keith saw

her in 1871. During the previous eighteen months the tumour had increased rapidly and she had suffered intensely, being almost entirely confined to bed. Dr. Keith, after letting her rest two days after her journey, found her with a pulse of 156, and temp. 103°, extremely emaciated and blanched. The tumour was above the umbilicus, and fluctuated; below it felt solid, and the abdominal wall was thick, hard, and oedematous, and in places even the skin seemed adherent. Three days later, three gallons of thick pus were removed by tapping above the umbilicus, with much relief, but a large firm tumour remained below. In three weeks the cyst had refilled, the pulse was rapid and feeble, temp. 103° to 104°; the skin was dry and shrivelled. Ovariectomy was performed. The adhesions were very extensive, thick, and vascular. The lower semi-solid part was firmly adherent in the pelvis, and posteriorly there were extensive intestinal adhesions. After the removal of the tumour, large flakes of old lymph like cartilage were peeled off. All bleeding points were secured with Lister's catgut; the pedicle was secured by clamp, and the wound closed with silk sutures. The operation lasted upwards of an hour, and much blood was lost. For many days she was in an extremely weak and critical condition; and in the third week a collection of serous fluid formed in the right iliac fossa, and was punctured. We have not space for the interesting details of the case; but in five weeks she returned home, and is now a strong healthy woman.

Case 2. *Recovery.* The patient was aged forty, and had been tapped by Dr. Keith two months before. Shivering, pain, and tenderness, with a pulse of 120, the temperature 102°, and dry red tongue, announced suppuration, and caused him to advocate immediate ovariectomy. Extensive and firm parietal, omental, mesenteric, and intestinal adhesions were separated, as well as adhesions to the rectum, and the bottom of Douglas's space. The cautery was used for dividing the pedicle. For forty-eight hours fever ran high, and the case seemed doubtful; then flatus passed freely, and she slept. Recovery was rapid, and she is now quite healthy.

Case 3. *Recovery.* This case is remarkable for the very low temperature, which, together with the general symptoms, led to suspicion of malignancy. The temperature was always below the normal, lower in the mouth than in the axilla. A second tapping gave two gallons of fetid pus, and revealed to Dr. Keith the true nature of the case. The tapping gave little relief, and the patient was, to all appearance, dying. On the morning of the operation the pulse could hardly be counted at 130; the temperature in the mouth was 95°. After clearing the cyst, the opening was closed by means of forceps and the whole held well forward; the operator's hands being well washed before proceeding to separate the adhesions, which were extensive. The cautery was used for dividing the pedicle. There was much oozing, and the wound was not closed for an hour and a half, when the sponges came out dry. She seemed almost dead when placed in bed; yet next morning the look of suffering was gone. In twenty-two hours flatus passed freely, and in four weeks she went home, and has enjoyed excellent health since.

Case 4. *Recovery.* This case, one of a young Canadian lady, aged twenty, is similar, both as to severity and difficulty of operation and result. The cautery was again used. Recovery was slower; and

there was free purulent discharge from a drainage-tube passing to a depth of six inches, beginning about the ninth day, and lasting for a fortnight. Her health has been excellent since her return to Canada.

Case 5. *Pyæmic fever; death from septicæmia three days after operation.* The patient was a large, fat, flabby, unhealthy woman aged fifty-three. She was tapped three times, and a fourth when suppuration had occurred. After a sixth tapping, the last chance was given her, though Dr. Keith thought unfavourably of her. The adhesions, as in the other cases, were very extensive, including the whole under surface of the liver and the gall-bladder. The cautery was used. Pressure by sponges to check oozing from hepatic adhesions caused much exposure of the abdominal cavity. For the first few hours her condition was very satisfactory, but at 5 A.M. next morning a change for the worse set in, with severe catching pain over the liver; and though there was some slight improvement on the second night, she gradually sank and died at the end of the third day.

Case 6. — *Recovery.* This is a remarkable case, in which a suppurating cyst burst into the peritoneal cavity, bringing the patient to the very verge of death. Dr. Keith tapped, and squeezed out two basinfuls of pus, etc.; and she so far rallied, that he thought it right in a fortnight to give her the chance of operation. The operation was like the others prolonged (two-and-a-half hours) from extensive adhesions, etc. A glass drainage-tube was left in, passing to the bottom of the pelvis behind the uterus; a sponge was placed over this, and it was cleared at intervals by suction, the fluid coming away being gradually freer from blood. On the third day it was removed, but was reintroduced on the fifth, and an ounce and a half of putrid red serum removed. On the twenty-sixth day the wound was cicatrised, and the patient well, having lost all traces of chorea, from which she had suffered before the operation.

Case 7.—*Recovery.* This is a similar case to the others. The cautery was again used, and the wound kept open till all oozing had ceased. She was well in six weeks, recovery having been retarded by sitting at an open window and catching a severe pleurisy.

The two chronic cases are not given in detail. In both the pedicle was treated by the clamp; in one there were adhesions, in the other, none; both recovered well. Dr. Keith, in conclusion, points out how high the temperature was in the acute cases, and how it fell several degrees directly after operation. In two of the cases the temperature was, on the contrary, extremely low before the operation, and rose after it.

In one chronic and one acute case, there were no adhesions; in the others, they were of the gravest nature. In five of the cases the clamp was used, and in five the cautery. One died in each class. He does not think tapping is generally a cause of this acute suppuration in cysts, and points out that pain or tenderness must be generally regarded as an indication of mischief going on in the cyst. Inflammation and adhesions between the peritoneal surfaces generally occur with but little history of pain, and that of a transitory character.

The extreme feebleness of pulse and depression of vital powers which these cases present must not deter from operation; they are not so unfavourable as they seem. J. KNOWSLEY THORNTON.

REVIEW.

Clinique Médicale. Par le Dr. NÖEL GUENEAU DE MUSSY, Médecin de l'Hôtel-Dieu, Membre de l'Académie de Médecine, etc. Tome I. Paris: Adrien Delahaye. 1874, pp. 675.

[*Clinical Lectures.* By Dr. NÖEL GUENEAU DE MUSSY, Physician to the Hôtel-Dieu, Paris, Member of the Academy of Medicine, etc. Vol. I.]

We had the pleasure of listening to some of these clinical lectures whilst on a brief visit to the hospitals of Paris in 1866, and many of them have from time to time been published in French medical journals. We are, therefore, glad to see them collected in this handsome octavo volume, and trust this first instalment will be speedily followed by other volumes. This is not a mere reprint. Each lecture has undergone a careful revision, and the author has been ably assisted in his task by Drs. Fernie and Labadie-Lagrave. He dedicates it to the memory of his ancestors, A. C. Lorry* and J. N. Hallé. It would be neither just nor decorous to make any comparison between these clinical lectures and those of either Graves or Trousseau. They have a character of their own, and, if less brilliant than those, are not deficient in either interest or eloquence. There is a closeness of thought and solidity about them which is almost English, whilst their clear, intelligible language and orderly arrangement are eminently French. M. Gueneau de Mussy is a scholar, well versed in the history of medicine, and has largely availed himself of the labours of continental, British, and American authors. He is magnanimous enough to give honour, when due, even to Germans, and the names of Skoda, Virchow, Wunderlich, Buhl, and Niemeyer, with others long familiar, are often met with in these pages: but his own observations prove that he is an excellent observer, a good clinical teacher, and a practical physician. As a specimen of his style, and of his acuteness as a clinical observer, our space only allows us to give the following example.

‘En 1849, j’ai indiqué un signe dont j’ai plus de quarante fois depuis vérifié l’exactitude, et qui peut faire reconnaître l’apoplexie pulmonaire, alors même qu’elle forme un noyau très-circonscrit, ou que, localisée dans le centre du poulmon, elle échappe à l’auscultation. Si, plus superficiel, le foyer hémorrhagique amène quelques modifications du bruit respiratoire, telles que la faiblesse de l’expansion, l’expiration prolongée, le souffle, le râle sous-crépitant, en l’absence de crachats hémoptoïques, ce signe peut déterminer la signification de ces phénomènes et fixer le diagnostic.

‘C’est une odeur toute spéciale de l’haleine, aigre et alliée à la fois, qui rappelle la teinte de raifort et qui est celle que l’on retrouve après la mort quand on flaire un de ces foyers apoplectiques. Elle est due à l’altération que le sang infiltré dans le poulmon

* Dr. Anne-Charles Lorry was born near Paris in 1725; gained his diploma of M.D. at the age of twenty-three; and died in 1783. He published a treatise on skin-diseases, remarkable for its learning, accurate observations, methodical arrangement, and clearness of diction: also an edition of the aphorisms of Hippocrates, with notes, etc. [Paris: P. G. Cavellier, 1759] and other works; and had sketched the idea of a book to be called ‘De mutationibus et conversionibus morborum’—which Gueneau de Mussy justly calls ‘a magnificent title.’ Lorry’s death prevented its completion.

subit au contact de l'air, et suivant l'étendue du foyer, cette odeur pourra être perçue à une grande distance, ou il faudra approcher le nez du malade pour la sentir; dans certains cas même, elle serait intermittente. On conçoit que des infiltrations sanguines des gencives pourraient donner naissance à une odeur semblable. Mais, dans ce cas, l'erreur serait facile à éviter.' This is followed by illustrative cases. There is a mass of interesting material in this volume, as will appear from the titles given in the foot-note.* The lectures on hysterical paresis, on the pitch of percussion-sounds, diaphragmatic pleurisy, the arthritic diathesis, and especially that on bronchial adenopathy, are perhaps the best, where all, or almost all is good. The author will pardon us for reminding him that the effects of posture on the pulse, in regard to which he seems to claim priority, were first pointed out by Dr. Marshall Hall, and were investigated many years ago by Dr. Guy, of King's College.

Dr. Gueneau de Mussy pays great attention to therapeutics. His remarks on the choice of remedies for anæmia, on the use of mineral waters, on the disadvantages of silvering pills, and the like, abundantly prove the study he has devoted to this too oft neglected department of medicine. Amongst the remedies highly prized by him in arthritic, dyspeptic, tuberculous, scrofulous, and some anæmic cases is the mineral water of La Bourboule, which issues from the soil near Mont Doré, rich in arsenate of sodium, containing, according to Thénard, twenty milligrammes of this salt in each litre. The composition of the water, according to later analyses, is as follows:

	Grammes per litre.	Grains per gallon.
Arsenate of sodium }	0.014 to 0.020	0.98 to 1.27
Chloride of sodium }	3.34	234.5
Bicarbonate of sodium }	2.27	159
Carbonic Acid }	0.38	26.6

'A composition which may justly be considered unique, as far as all the other European spas are concerned.' A foot-note to p. 246 has the following sensible remarks on prescribing.

'Because, in by-gone times, the most heterogenous mixtures were used, or rather abused, in medicine, some physicians cover with ridicule, and seek to crush under the nickname of polypharmacy, the combination in a prescription of medicines not chemically incompatible, and tending to one end. This exclusiveness, now very prevalent in Paris, does not commend itself to my mind as logical. If you are experimenting on the action of a given remedy, isolate it by all means, as perfectly as possible; but if your object be to benefit your patient by using

drugs whose action you believe you know, what possible objection can there be to combining them, if not chemically incompatible, and if the stomach will tolerate the compound? In a battle all sorts of weapons are used simultaneously, and their action is concentrated on the point judged most important. This pharmaceutical purism seems to me exaggerated; but I must not be understood as recommending mixtures when a single drug is sufficient, or as wishing to recur to the age of elixirs and electuaries. *In medio stat virtus.*'

The publishers have evidently taken great care in the printing, and the editors in revision, for the number of misprints is exceedingly small.

W. B. WOODMAN, M.D.

MISCELLANY.

THE ROYAL IRISH ACADEMY has given its sanction to the following grants, among others, from the fund placed at its disposal for aiding scientific researches by providing suitable instruments and materials:—25% to Dr. Handsel Griffiths, for 'Experiments on the Effects of Certain Drugs on the Circulation,' and 25% to Dr. Reuben Harvey, for 'Researches on Staining Reagents used in Histology.'

GIRLS OF THE PERIOD.—The following strongly contrasted sketches of 'the English Girl and the American Young Lady' are taken from a review in the *American Quarterly Journal of the Medical Sciences* for January, of a work on primary education called *The Building of a Brain*, by Dr. Clarke, of Boston, the author of *Sex in Education*. The reviewer begins by stating that in English schools for girls the diet is simpler and more nutritious than in similar American establishments; that the meals are better arranged and that more time is allowed for them, and that out-door exercise is more strongly insisted on. Sleep is closely attended to; girls of seventeen or eighteen are usually sent to bed at nine o'clock; in many schools no books are allowed after eight. 'Tranquillity of life is enforced; up to eighteen the girl sees almost nothing of society, even in her own home. She does not frequent public entertainments, and knows little and cares less what is going on in the outer world. Especially is she free, at school or home, from pernicious rivalry and competition. No public examinations or graduations are dreamed of. Her tasks are lighter than those of her brothers, and she never comes into competition with them. Public opinion places a higher estimation upon sound vigorous health than with us. Sickliness and pallor are not admired; young men seek healthy wives, not interesting invalids. What a contrast does this picture present to what we daily see around us. The hearty, simple-minded, ruddy English girl, fed and exercised with a care which *we*—shame to us—give only to our fast horses, remaining a girl till nature has fully transformed her into a woman, and then blooming into a noble womanhood with a capacity perfectly to discharge her duties in all relations. On the other hand the thin and haggard, or pallid and puffy damsel, hard-studying, meal neglecting, chocolate-eating, pickle-devouring, sleep-contemning, who despises walking exercise, who in cold weather spreads her skirts over the scorching blasts of the "register," and who will go to her parties and balls even if obliged to plunge her feet into ice-water to arrest a vexatious function! Look at the girl and woman on the one side and at the factitious "young lady" on the other, and see which promises best to the land that breeds them.'

* The subjects included in this volume are, after some introductory chapters on the principles of clinical medicine and therapeutics: Congestion, in general, and Menstrual Congestion, in particular; Derivation in Medicine; Insomnia, Vertigo; Mercurial Tremors; Hysterical Paralysis; Paresis of the Third Nerve; Perineuritis Optica and Retinal Apoplexy; Tumour of Brain; Lead-Palsy; Reflex Sensibility; Chlorosis; Public Health; Rheumatism, Acute and Chronic; Gout; Atheroma of Arteries; the Arthritic Diathesis; Pericarditis; Heart-Disease; Thoracic Aneurisms; Asthma and Pulmonary Tuberculosis; Cauterisation of the Larynx; Phthisis; Emphysema; Hay-Asthma; Bronchial Adenopathy; Cough; Tonality or Pitch of the Organic Sounds; Modifications of the Diameter of the Chest; Diaphragmatic Pleurisy; and Thoracentesis in Effusions of long standing.

THE MORTALITY AMONG 'RHEUMATIC RISKS.'—The *New York Medical Record* for March 13 contains an interesting paper by Dr. Huntingdon on the rate of mortality which exists among what are called in life-assurance phraseology 'rheumatic risks,' that is among those policy-holders who in filling up their proposal papers are obliged

to confess to having suffered from some form of rheumatism, from 'slight muscular' to 'acute inflammatory.' On searching the records of his office he found 844 such 'cases, and among these 114 deaths had occurred. The average age at death of these 114 policy holders was forty-six years nine months. As regards the causes of death, 21 out of 114 (18.42 per cent.) died of heart disease; 22 (19.29 per cent.) of brain disease and 4 (3.5 per cent.) of dropsy; doubtless many of these deaths from 'brain disease' and dropsy were also due to heart disease. Among the policy-holders who at the time of their acceptance had, according to their own account, never suffered from rheumatism, the deaths from heart disease were under 4 per cent; those from brain disease were 11.39, and from dropsy 1.8; the number of deaths from these causes among all the insured being respectively 5.6, 12.3 and 2 per cent. Taking into consideration the ages at the time of insurance, the mortality amongst these rheumatic risks should have been 30.57 per 1,000, the actual mortality was 54; and even amongst those who confessed only to 'slight occasional' pains the mortality was 31 instead of 29.35. Some allowance must probably be made from these figures, not only for a few cases of intentional misrepresentation, but also for the great tendency to make light of these ailments which is common among presumably honest applicants for insurance; otherwise these results would seem to prove that even a slight tendency to rheumatism is a more serious matter than it has been hitherto considered by the profession in general. And, since cases of well-marked rheumatic diathesis are refused by all offices, and consequently do not appear in the above returns, it follows that great caution is necessary on the part of life offices in accepting any rheumatic subject; though, as Dr. Huntingdon says, 'Rheumatism is so common that were we arbitrarily to exclude all who say they have had it life offices would scarcely be able to do business.'

MARRIAGE OF COUSINS.—Mr. Darwin lately read a paper before the Statistical Society on marriages between first cousins in England and their effects. The subject was divided into three separate heads—(1) the proportion of first cousin marriages to all marriages; (2) inquiries in asylums as to the harm likely to arise from such marriages; (3) literature on the subject. With regard to the first it would appear from a series of carefully prepared statistics, compiled from Burke's *Landed Gentry*, the 'English and Irish Peerage,' and the General Registry of Marriages at Somerset House, that such marriages are in London, including all classes, about 1½ per cent.; in the urban districts about 2 per cent.; in the rural districts about 2¼ per cent.; in the landed gentry about 3½ per cent.; and in the aristocracy, probably 4½ per cent. Answers with respect to the parentage of 4,308 out of 8,170 patients in lunatic and other asylums and hospitals were obtained; 142 to 149 of these were stated to be offspring of first cousins, that is to say, nearly 3½ per cent. Similarly, out of 514 patients in Scotland, 5½ per cent. were found to be offspring of first cousins. From the fact, then, that the percentage of offspring of first-cousin marriages is so nearly that of such marriages in the general population, the negative conclusion only is to be drawn that, as far as insanity and idiocy go, no evil has been shown to accrue from consanguineous marriages. Mr. Darwin was of opinion that the percentage of such offspring in asylums is not greater than that in the general population to such an extent as to enable any one to say positively that the marriage of first cousins has any effect in the production of insanity or idiocy, although it might still be shown, by more accurate methods of research, that it is so. With respect to deaf mutes, the proportion of first-cousin marriages is precisely the same as the proportion of such marriages for the large towns in the country. On the third head of his subject, the lecturer stated that the most thorough investigation ever made was contained in some papers *On Blood Relationship in Marriage*, published by Dr. Arthur Mitchell, a Deputy Commissioner for Lunacy in Scotland. This gentleman's inquiries were confined

chiefly to Scotland, in which country the proportion of first-cousin marriages is larger than in any other portion of the United Kingdom; and the conclusion he arrived at was that, under favourable conditions of life, the apparent ill-effects were frequently almost *nil*, while if the children were ill-fed, badly housed and clothed, the evil might become very marked. This, said the lecturer, was in striking accordance with some unpublished experiments of his father's, 'On the In-and-in Breeding of Plants,' in which he found that in-bred plants, when allowed space enough and good soil, would frequently show little or no deterioration; but when placed in competition with another plant, would frequently become stunted or altogether perish. Reference was also made to a work by Professor Mantegazza of Pavia, on the same subject, in which it is contended that consanguineous marriages are, on the whole, more unfavourable to the offspring than others, and that the nearer the kinship the greater the danger. Mr. Buxton, of the Liverpool Institution for the Deaf and Dumb, in the *Medico-Chirurgical Journal* for January, 1859, found one deaf mute in ten to be the child of first cousins; Dr. Peet, of the New York Institution, gives the same proportion; Mr. Lewellyn Pratt, in the *American Annual of the Deaf and Dumb*, January, 1869, found that out of 110 deaf-mute children in Halifax School, fifty-six were the offspring of first cousins; and Sir W. Wilde, discussing in an appendix to his *Aural Surgery* the causes of deaf-muteness, considers consanguinity may be regarded as paramount. In conclusion, Mr. Darwin held that such a general consent as to the ill-effects of cousin marriages would have far greater weight than his 'purely negative' results. But in no case had the investigation been free from flaws, for in no case had it been really determined what was the proportion of consanguineous marriages in the whole population. He trusted, however, that though he himself had been unable to give a satisfactory solution of the question he had raised, he had said enough to show that the assertion that the question had been already set at rest could not be sustained, and he hoped that his endeavour might lead more competent investigators to take it up from some other side.

THE GAS QUESTION.—The attention of our readers is earnestly invited to a modern invention, by adopting which they will be able to dispense with gas in daytime, thereby evading the advance imposed upon consumers by the various companies. The invention we allude to is Chappuis' Patent Daylight Reflectors, manufactured at 69 Fleet Street, London.—[ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.: free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, APRIL 14, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

PANUM ON THE NUTRITIVE VALUE OF ALBUMINATES FROM THE BLOOD AND OF MEAT-SALTS.

Panum (*Nordiskt Mediciniskt Arkiv*, vol. vi. no. 19) doubts the validity of the conclusions of Liebig, Kemmerich, and Lehmann, on the nutritive value of the salts contained in meat, and the alleged uselessness without them of the albuminous residues left in the manufacture of extract of meat.

To investigate this point, he fed dogs on varied diet, either composed of meat alone or with starchy matters, fat and salts, or else of barley-broth, etc., without meat, and compared the results thus obtained with those gained by feeding the animals on powdered albuminous matters, without salts, obtained from blood by a special process; these being mixed or not with starch, fat, water, etc., and either with or without the addition of the 'meat-salts' and table-salt.

[The albuminous matters were obtained from ox-blood by diluting it with water, boiling, neutralising with a small quantity of acetic acid, and filtering; the mass being then pressed, completely dried and ground, and the whole process occupying only a few hours. The powder thus obtained will keep unchanged for years; it contains 10 per cent. of water, and 1 per cent. only of ash.]

The 'meat-salts' given were thus composed: 30.36 per cent. potash, 26.88 per cent. phosphoric acid, 19.25 per cent. soda, 23.52 per cent. chlorine.

[The variations in the weight of the animals were very carefully taken, as also the quantities of food-salts, etc., consumed, and of fæces, urine, urea passed, both on certain days of total abstinence, and when placed on different diets. It was found very necessary to humour the appetite of the animals.]

The chief results were as follows. 1. A certain quantity (about 8 per cent.) of the powdered albuminates given as food passes away with the excrement, but the greater part (92 per cent.) is received into the blood for nutrition. 2. Eighty-four grains of this powder appears to be equivalent, as measured by the amount of urea produced to 375 grains of dry horseflesh. 3. Carbon contained in albuminous matters (and especially in this form) is more valuable in preserving the weight of the body than the carbon in starch or fat. The loss by insensible perspiration is much greater after eating starch or fat than after albuminous matters, perhaps from more rapid combustion in the latter case. When powdered albuminates are compared with a diet of barley and fat, the difference is in the proportion of two to one. 4. The addition of phosphate of potash to a diet composed of the powdered albuminates with starch, fat and water, did not increase its nutritive value, as shown either by the production of urea, or in preserving the

weight of the body. The chief result was that the animal drank more water, and lost more by insensible perspiration. 5. A dog may be kept in good health on a mixture of barley, fat, water and common salt, for more than three months, showing that this diet contains sufficient salts. It was also found that the deficiency of salts in the powdered albuminates could be perfectly supplied by barley. 6. The powdered albuminates have a marked effect in augmenting the colouring matter of the blood-corpuscles, while this is diminished by a non-nitrogenous diet (starch, fat, and water). 7. It is possible, and even *à priori* very likely, that a certain quantity of phosphates and of potash is a necessary part of food; but this quantity must be very small, since grain, such as barley, contains enough to compensate the deficiencies of another diet in this respect.

The author did not see, till after his own researches were concluded, the memoir of Forster, in which it is shown that a certain quantity of the salts proper to the organism is a necessary constituent of food. In respect of the quantity, Forster's conclusions do not conflict with those of Panum, since both agree that the necessary amount is extremely small, and that it is found in almost all articles of food.

J. F. PAYNE, M.B.

BERNHARDT ON PROGRESSIVE MUSCULAR ATROPHY.

At a meeting of the Medical Society of Berlin (*Berliner Klinische Wochenschrift*, March 8 and 15, 1875) Dr. Bernhardt described two cases of progressive muscular atrophy occurring in the same family, in which also other instances of the same fatal malady had been met with. In the younger of the two brothers, the disease was in an earlier stage. The younger brother (Otto) was eleven years and nine months old. His size was about the average for his age, and beyond that of general weakness he made no complaint. His appetite was normal and digestion good; he slept soundly. He was, however, only slightly built, and his muscular system was feeble. The skin was soft and pale. His integuments, especially about the thighs, were mottled; the hands and feet also occasionally became faintly cyanosed; the temperature of the surface was normal. Nothing particular was observable in the shape of the skull. The organs of sense were intact. The voice and speech and deglutition were also perfect. The muscles of the upper extremity, and of the neck and chest, were but slightly developed. The circumference of the arm at the insertion of the deltoid was fifteen centimètres (5.86 inches); of the forearm, a hand's breadth below the elbow-joint, fifteen and a quarter centimètres (5.95 inches); the muscles of the hand were well developed, and all the finer movements, such as in writing, etc., were perfectly performed. The muscles of the thigh were not wasted. The calf felt firm but not unduly hard. Both feet had a slight degree of *talipes equinus* malformation. He could stand alone, but straddling, stepping on his toes, with the heels raised from the ground. Both shoulder-blades projected backwards. In the erect posture, a curvature of the spine was very evident in the lumbar region. When sitting, he could only rise by giving his body a swing, so as to bring both shoulders forward. When recumbent, he could with difficulty move his head from the horizontal position. The joints from the hip to the toes were severally movable, but their combined movements

were not easily performed. To rise from the recumbent posture, he exerted himself to a peculiar movement of the entire trunk from side to side, supporting himself with his hands on the floor, flexing the thighs on the body, and then with hands and arms climbing up from the ground. His gait was waddling, and the slightest obstruction caused him to fall. The electrical excitability of the muscles was depressed.

The next case was the elder brother of the preceding patient.

H. M., aged sixteen, went about like other boys until he was ten years old. For the last five years he had been altogether confined to the house. He was reduced almost to a skeleton, his muscular and bony structure being highly defective. He was free from fever. His intellect, owing to his illness and external relations, was imperfectly developed; still he could read and write and converse with those around him, and express his thanks for attentions and kindness. He slept well, had a good appetite, and his bowels and bladder acted with regularity. His head was large, his ears prominent, the lobe of the left ear most so. The organs of sense were unimpaired. The expression of the countenance was dull and unsympathetic. The head moved freely to either side. The left shoulder was rather depressed compared with the right. The vertebral column was curved, with its convexity to the right, in the dorsal region. The circumference of the upper arms was about equal, viz., twelve and a-half and thirteen centimètres (4·9 and 5·1 inches) round the upper third. If the patient reclined his occiput upon anything, he could not again raise it without help; nor could he raise or rotate the arms at the shoulder-joints. Both forearms were somewhat bent upon the arms. Slight movements of pronation and supination were effected with ease, but flexion was impeded. The muscles of the ball of the thumb and interosseous spaces were wasted. The thighs were bent on the pelvis and resisted flexion. The adductor muscles were not contractile. The feet had the *pes equinus* deformity. The measurement of the middle of the left thigh was 18½ centimètres, of the right, 18½ centimètres (about 7·1 to 7·2 inches). The right calf measured 17½ centimètres (6·8 inches), the left 18½ centimètres (7·1 inches). The standing position was impossible. For the last five years the patient had been confined to the half-sitting, half-lying posture. The pelvis was displaced, so that the left iliac spine was higher than the right. The trunk could not be raised from the recumbent posture without help. Locomotion was only performed by alternately stretching and bending the lower extremities. He moved his feet and toes freely.

The skin was throughout white and soft. The infraclavicular fossæ were deep. The pectoral muscles seemed to be wanting. The pulsations of the subclavians could be seen distinctly. The thorax was flat; the intercostal spaces wide, their furrows scarcely perceptible. The impulse of the apex of the heart was visible in the fourth and fifth intercostal spaces. Synchronous with this an impulse was visible in the second left intercostal space; at this point also a systolic tremor could be felt, and a diastolic murmur was audible. The radial pulse varied from 90 to 100, was feeble and compressible. A systolic murmur was audible in the carotids. Some mucous râles were heard in the lungs. The patient had had cough for some time. The sensibility of the integuments, so far as it could be made out,

appeared normal. The electrical excitability of the muscles was greatly lowered.

The patient's father had not suffered from any similar affection. He had died at the age of thirty-eight from some chest-affection. The mother was still living, healthy, and active. Seven sons (no daughters) had been born to these parents, of whom four were living. Two of these, aged respectively twenty and twenty-two, were healthy. Two others were invalids, and had already been spoken of. Three brothers, who died from a similar malady, sank from disease of the lungs. The father, mother, brother and sister of the parents were alive and perfectly healthy, as were also their offspring. Hence no hereditary tendency could be shown, nor could the influence of adverse external circumstances account for the appearance of the affection in these individuals, since the family were prosperous landed proprietors.

The children, one and all, including the deceased, learned to walk at the ordinary time, although there had always been a peculiarity in the gait of the children referred to.

Dr. Bernhardt observed that there were here seven sons of parents not the subjects of any nervous affections, of whom five were the victims of this malady, and to which three had succumbed. A tendency to the disease, and its appearance in several members of the same family, had often been noticed (see Friedrich *On Progressive Muscular Atrophy*), in progressive muscular atrophy, and in pseudo-muscular hypertrophy.

A question here suggested itself, whether, considering the relative size of the calves and the glutæi, and the slight degree of atrophy of other muscles of the body, these cases should be regarded as cases of progressive muscular atrophy, or of pseudo-muscular hypertrophy. Unfortunately, the mother had not noticed the state of the muscles of the calves in the other children. If, however, it were remembered, that cases of pseudo-hypertrophy seldom occurred without more or less atrophy of some of the other muscles; and if it were borne in mind that, according to the latest investigations, no essential difference exists in the condition of the muscles, but that the apparent difference is dependent upon secondary circumstances, it would not be necessary to enter into controversy upon mere names, but the views of Friedrich might be adopted, that both are modified forms of myopathic disease.

W. B. KESTEVEN.

LEFFERTS ON THE REMOVAL OF A BRASS RING LODGED IN THE LARYNX FOR FOUR YEARS.

Dr. Lefferts describes, in the *New York Medical Record*, an interesting case in which he removed a foreign body from the larynx by subhyoidan laryngotomy.

The patient, a child six and a half years old, came under Dr. Lefferts' notice in the summer of 1874 suffering from aphonia, and from serious and protracted attacks of laryngeal spasm. Four years previously she had accidentally swallowed a small ring, about the size and thickness of a modern wedding ring, but which, after its removal, was ascertained to be a locket-ring made in one piece, with a division at one portion of the circle. Urgent dyspnoea immediately followed; the child became

cyanotic and unconscious, and suffocation seemed imminent, until one of the bystanders, passing her fingers deeply into the child's throat, felt the ring and pushed it downwards. This act was followed by immediate improvement in the respiration. The child recovered consciousness, and soon afterwards was able to run about and play. On the physician's arrival, a short time later, various instruments were passed into the throat in order to seize the ring, but without success; and, no foreign body being met with during the examination, it was supposed to have passed into the stomach, and further attempts at removal were abandoned. Cathartics were administered, and the evacuations were carefully watched, but the missing body was not found. The child's respiration is stated to have remained good during the rest of the day of the accident, but the same night the mother noticed that it was decidedly stridulous, and said that it since remained so. The child, however, had not had any attacks of laryngeal spasm. Deglutition had not been affected. Immediately after the accident the child became partially aphonic, and continued subsequently in the same condition.

When seen by Dr. Lefferts she was suffering from frequent paroxysms of dyspnoea, was aphonic, and had a short hacking cough, which had commenced a few hours after the ring was swallowed, and persisted since that time. A laryngoscopic examination showed two-thirds of the ring lying obliquely across the larynx. One extremity of the ring appeared to pass downwards and forwards at the middle-third of the left ventricular band, the circle of the ring being continued backwards and upwards to the pharyngeal wall over the arytenoid commissure, then forward to the hyoid fossa, where it was lost to view. The ring thus encircled the left ary-epiglottic fold and ventricular band; but, except where it passed deeply into the tissues, it did not come into contact with the larynx. The ary-epiglottic fold was swollen and œdematous, and the ventricular band irregular and thickened. The ring had undergone little corrosion but was in parts discoloured. Owing to the tender age and nervous temperament of the patient, it was impossible to secure the co-operation necessary for laryngoscopic treatment. Repeated laryngoscopic examinations, made under great difficulties, furnished the most important evidence as to the exact situation of the foreign body. On July 7, 1874, after first inserting a cannula in the trachea, Dr. Lefferts performed subhyoidan laryngotomy. An incision three inches in length was made parallel with the lower border of the hyoid bone, and one inch below it, transversely across the neck; and, the tissues being carefully divided on each side of the median line upon a director, introduced successfully between the various layers, the thyro-hyoid membrane was reached and laid bare without difficulty, and with very little hæmorrhage. Two rather large veins, which lay across the track of the wound, immediately below the platysma, were tied. The thyrohyoid membrane was now divided by an incision of less extent than the one through the superficial parts; and a funnel shape being thus given to the wound, the cushion of cellular and adipose tissue lying between the base of the epiglottis and the parts external to it, together with the laryngeal mucous membrane on each side of it, were disclosed; the latter was prolapsed outwards, as soon as the tense pressure of the thyro-hyoid membrane was removed, and could be seen to be drawn inward

with each inspiration. After having reached this point in the operation, Dr. Lefferts inserted a tenaculum into the cellular and adipose mass, and by means of it drew the epiglottis forcibly downwards. This put its ligamentous attachments to the hyoid-bone and tongue upon the stretch, drew it away from the former, and left an appreciable interval of space between them, through which the knife—its point directed upwards and backwards, and kept near the hyoid bone—was readily passed, and was found to have penetrated the mucous membrane between the tongue and the epiglottis. An excellent view of the upper part of the larynx was obtained, and the ring, on being rotated, was easily removed through the external opening. The wound was at once closed by sutures, the divided edges of the mucous membrane having been first brought together by fine thread sutures, the knots of which were tied so as to lie inwards. Owing to slight inflammation of the epiglottis, the tracheal tube could not be dispensed with till the thirteenth day. The wound healed on the twenty-first day, and the patient was discharged 'cured,' though the voice does not appear to have been quite normal at the time.

[This case is reported in considerable detail for several reasons. Not only is it the first recorded case in which subhyoidan laryngotomy has been performed for the removal of a foreign body; but Dr. Lefferts has considerably modified the method of operation as recommended by Malgaigne, and has shown that it is possible to obtain a most satisfactory view of the larynx by subhyoidan laryngotomy without wounding the epiglottis. In a similar case in an adult it would probably be better to perform tracheotomy, and then remove the foreign body *per vias naturales*; but in the case here detailed, no doubt the plan pursued by Dr. Lefferts was the very best that could have been adopted, and the mode of carrying it out reflects great credit on the operator. —*Rep.*]

LAUNSCHIRM ON METRORRHAGIA AFTER ABORTION, IN THE FIRST HALF OF GESTATION, ENDANGERING LIFE, WITH RETENTION OF THE PLACENTA.

In an article communicated by Dr. Launschirm to the *Medinisch-Chirurgisches Centralblatt* for January 1 and 8, 1875, he says that Lumpe, when speaking of placenta prævia, remarks that 'the first drops of that ceaseless stream of blood arouses with its fearful foreboding the medical practitioner, to the working of that incurable cause; with un-wished-for fidelity his memory recalls misfortunes experienced under similar circumstances. He requires his whole moral strength, steelled by firm self-reliance on the oft-tried capability of action, and a habit of looking danger calmly in the face, in order to secure that calmness of reflection, discretion and courage in action, without which the (scientific) accoucheur ought never to approach the bedside; without these qualities his work may be equally as injurious, nay, murderous, as with them it may be beneficent in its action.'

Those who have had experience in like cases can realise the fidelity and truthfulness of this description and the enormity of the peril.

In the middle of the night the writer was summoned to the wife of a professional brother who had aborted two days previously, without any excessive

loss of blood. During the absence of her husband on the second day, she had got up and proceeded to attend to her household duties; towards evening, on account of the continued pains and flow of blood which had set in towards midday, she was compelled to go to bed, when she fainted. On her husband's return in the evening, he injected ice-water into the vagina, plugged it with cotton-wool steeped in a solution of perchloride of iron, and applied cold-water fomentations to the abdomen, all without the least benefit. In the meantime, the hæmorrhage increased in violence, and the fainting fits became more frequent. Dr. Launschirm found the patient in a state of extreme collapse from loss of blood; in fact, it was hardly possible to imagine a higher degree of anæmia compatible with life. A vaginal examination showed that passage to be filled with coagula, in addition to the tampon. The external and internal os allowed the introduction of the forefinger. The body of the uterus was made out to be enlarged, probably distended with blood and the secundines, with the lower segment narrowed and contracted. This exploration renewed the hæmorrhage, which had somewhat diminished: to have at once proceeded to empty the uterus of its contents would have been to have snuffed out the life of the patient. Measures had to be directed to counteract the imminently fatal collapse by restoratives, and to reduce the strong uterine contractions of that distended organ to a minimum, and also to arrest the consequent hæmorrhage for a short time, in order that the patient might recover a little. This was attained by introducing Braun's colpeurynter into the vagina, distending it with ice-water, and renewing the contents every half-hour; at the same time giving table-spoonful doses of mulled wine every five minutes, and a hypodermic injection of morphia was also made over the pubes. The hiccough, which was very distressing, was treated with iced soda-water and small lumps of ice. The vomiting was removed, but heartburn ensued. With the exception of ice and soda-water, all medication was withdrawn; a solution of warm wine and camphor was applied to the pit of the stomach by means of wet cloths, and beneath the arm-pits and the bends of the large joints. This method Dr. Launschirm strongly advises in extreme collapse, when the stomach refuses to retain nourishment.

This treatment had the desired effect; the temperature rose, the heart-beats became stronger and rhythmical, the sickness ceased, and the hiccough less; the uterine contractions less frequent, and the hæmorrhage almost entirely stopped. At noon on the next day he proceeded to empty the uterus of its contents. The colpeurynter was withdrawn, and with it came a dark, almost black clot, which from its consistence and form had evidently not been formed between the caoutchouc bag and the uterus by the blood trickling down, but had been expelled from the uterus. The os was considerably wider, admitting the fore and middle fingers into the cavity of the uterus. Six introductions of the fingers were necessary, entirely to remove the contents of the organ; with the last was brought away a rudimentary placenta attached to the normal placental site. A tightly drawn abdominal binder was applied, in order to prevent hæmorrhage and favour involution of the uterus. [According to the doctrine of the American accoucheurs, a tightly drawn binder maintained for any period beyond thirty-six hours, acts as an impediment to involution

by preventing the backward flow of blood and causing hyperæmia of the placental site.—*Rep.*] The treatment had to be applied with great care, as any movement of the patient caused fainting. To relieve the anæmia of the brain the foot of the bed was raised half a foot with the most gratifying results. Quinine was administered internally, and at a later period of convalescence iron was added. The patient made a good and rapid recovery.

The author incidentally remarks that the process of involution after abortion is retarded and irregular. The metrorrhagia in this instance is viewed by the writer as an autochthonous process, rising neither from any known extraneous influence nor from any demonstrable essential disease of the uterus, nor from any previous acquired physical changes, but from an intense hyperæmia, with superadded uterine contractions. As a sequence thereon, a rupture of the utero-placental vessels might be considered probable, which took place, at first, perhaps a week before the death of the fœtus and expulsion of the child, and which occasioned the hæmorrhage. These suppositions are supported by:

1. The relative good health of the patient up to eight or ten days before the abortion;
2. The tumour in the abdominal region not having been previously perceptible;
3. That about eight days before the expulsion of the ovum she became unwell, with perceptible painful uterine contractions, compelling the patient to keep her bed for a few days;
4. The colour, consistence, and quantity of the blood found in the cavity of the uterus;
5. The proved enlargement of the uterus made out by the bimanual examination after the abortion, and the then already life-endangering bleeding.

A displacement of the uterus was possible, which tended to produce, in an extreme measure, hyperæmia of the organ, acting mechanically on the process of gestation. It might have been present before the introduction of the colpeurynter, which may have reduced it.

Worthy of note was the range of temperature which, when its body was cold and pulseless, was not lower than 94° Fahr., and which rose to 98·6° Fahr. as soon as the patient showed signs of reviving; fluctuating, however, between 95° and 98·6° Fahr. during the interval of observation.

W. C. GRIGG, M.D.

ANATOMY AND PHYSIOLOGY.

MAYER ON RESPIRATORY MOVEMENTS.—It has been observed, that by the stimulation of certain inhibitory nerves in the vagus, a longer or shorter pause of the heart's action is produced. The disturbances thus caused in the normal circulation, Dr. Sigmund Mayer has utilised in study of some questions connected with respiration (*Sitzungsberichte* of Vienna Academy, Band lxi.).

The experiments were made on dogs; (for details of the method, we must refer to the memoir). A stoppage of the heart, lasting at least eight to ten minutes, can be produced as indicated. It is best to stimulate the right vagus, as this has a greater inhibitory action than the left. During the heart-pause, the respirations become quicker and deeper. If, now, the stimulation be stopped, so that, with returning heart-contractions, the blood-pressure

quickly rises again to its former state, there follows on the deep and quick respirations, a complete stoppage of breathing, which may last for half a minute. If the stimulation of the vagus be continued so long that the heart begins again spontaneously to beat, though more seldom than before stimulation, it is found that the respirations, which had become quick and deep, now, on renewal of the heart-beats, are separated by long pauses, or entirely cease. If the stimulation be stopped after a short heart-pause has been produced, so that a series of quick pulses follows, and then the vagus be again stimulated, renewing the heart-pause, there follows a longer pause in the breathing. The experiments yield essentially similar results when, besides the vagus subjected to stimulation, that of the other side also is cut.

The stoppage of breathing is in the position of expiration. This is indicated by the curves, also by the fact that, in emerging from that state, the animal begins with an inspiratory movement.

Dr. Mayer offers the following explanation of the phenomena. By stoppage of the heart we stop the transmission of blood to the brain; and the blood, which now stagnates in the latter, becoming impoverished in oxygen, stimulates the respiratory centre, causing quicker and deeper respirations (dyspnœa).

But these quick and deep respirations have evidently the effect of an excessive arterialisation of the stagnating blood in the lungs (greater than can be produced by blowing air into lungs with a bellows). Now, when the heart begins to act again, a current of highly arterialised blood is sent to the brain-centres, and such (as has been shown) is not capable of causing respiratory movements. This stoppage of breathing is an apnœa which hitherto appears only to have been produced by injection of air with a bellows.

This method, the author points out, has advantages over that with bellows. It is more simple and direct. The change is wrought by the animal's own vital functions; and the effects of variation in the quantity of oxygen and carbonic acid in the blood upon the respiratory centre, are compressed into a comparatively short space of time.

He next brings evidence in support of his explanation. It has been shown before that dyspnœa can be produced by stoppage of the blood-circulation; some observers having done so by cutting off the supply of blood to the brain. Then as to the apnœa, produced by over arterialised blood; if the deep and quick respirations were, in some way, prevented from so affecting the blood, the cessation of breathing should be excluded. It is actually so: if the animal, during stoppage of its heart, be made to breathe, not free atmospheric air, but from an enclosed space, by a narrow connecting piece, rendering the exchange of gases difficult, there is no stoppage of respiration, and the dyspnœic effects continue. The same result is had, if, during stoppage of the heart, the trachea be closed.

Some might, perhaps, say that the apnœa is not due to direct influence of the highly arterialised blood on the respiratory centre in the brain; but to changed reflective action on that centre, through excitation conducted from the periphery, especially the excitation shown by Hering and Braun to arise from artificial inflation of the lung, and propagated by the vagi. In reply, Dr. Mayer points to the fact that the results were not affected though the second vagus was also cut. Besides, the animal emerges

out of its still state, in the other case (of inflation of the lungs), by an expiratory movement.

Dr. Mayer points out, that the above method of changing the velocity of the blood-current in the lungs may be variously used for regulating, within certain limits, the proportion of gases in the blood; further, that in all experiments on respiratory movements it is indispensable to have exact control over the action of the heart, so as to be able to distinguish the alterations in the breathing-movements produced by changes in the circulation, from those produced otherwise (nerve-stimulation, etc.); and lastly, that this method of making an animal apnœic is well suited for lecture experiments.

PATHOLOGY.

OGSTON ON CONGENITAL MALFORMATIONS OF THE LOWER JAW.—Dr. Ogston (*Glasgow Medical Journal*, July, 1874) has very carefully collected from various sources a number of cases of congenital malformation of the lower jaw. The chief authorities quoted are Vrolik, Otto, Langenbeck, and Smith of Dublin. A case occurring in the practice of Mr. De Lessert, of Aberdeen, is also given. Dr. Ogston has, however, overlooked two cases of arrested development of the ramus of the lower jaw; one recorded by Mr. Edwin Canton (*Pathological Society's Transactions*, vol. xii. 1861, p. 238), and a second specimen described by Mr. Charles S. Tomes in the *Transactions of the Odontological Society*, March, 1872.

After discussing the points of interest connected with each case, Dr. Ogston concludes as follows.

1. Congenital deformities of the lower jaw are very rare.
2. Non-development of the lower jaw has been recorded in animals, but never in man.
3. Excessive development of the lower jaw appears to occur, though very rarely, and minutely recorded cases of it do not exist.
4. Preponderance of size of the lower jaw has been observed as the result of deficient development of some of the other facial bones.
5. Congenital smallness of the lower jaw occurs, and is generally associated with symmetrical deformities elsewhere.
6. Congenital smallness of the lower jaw may lead in after-life to acquired deformities of the bones of the cranium and face.
7. Congenital unilateral smallness of the lower jaw has been found in one case with, and in two without, malformation of the temporo-maxillary articulation of the same side, and coincided in all with asymmetry of the cranium.
8. Congenital dislocation of the lower jaw is said to have been met with in a single imperfectly recorded case.

OAKLEY COLES.

VOURY ON MENIÈRE'S DISEASE.—Dr. Voury, in his *Thèse de Paris*, 1874, gives the following conclusions on this disease. It is an affection characterised by deafness, buzzing in the ears, and attacks of vertigo, generally accompanied by serious troubles of equilibrium, by a syncopal condition, nausea, and vomiting. The lesion is in the labyrinth; it is of a congestive, inflammatory, or traumatic nature. Menière's disease may either be primary, secondary, or traumatic. It should be distinguished from auricular vertigo simply by the serious character of the deafness upon which Menière has insisted, and which is the index of the lesion. The nervous accidents, according to the majority of physiologists, are probably phenomena of reflex action. The deafness

is incurable. Voury, however, in the course of his work, recommends the application of the actual cautery or a seton behind the ear, according to the advice of Professor Charcot, and bromide of potassium or chloral for the nervous symptoms.

MEDICINE.

BOUCHUT ON MEDICAL OPHTHALMOSCOPY AND CEREBROSCOPY.—M. Bouchut gave a special lecture at the Hôpital des Enfants Malades, of Paris, to a certain number of his professional brethren. As reported in *La France Médicale* of March 27, he first showed the anatomical and physiological relations of the eye with the brain or the spinal marrow, so as to make understood the influence of the cerebro-spinal lesions on the optic nerve, the retina, and the choroid. He then indicated the laws of the formation of intra-ocular lesions depending on diseases of the brain, spinal marrow, and meninges.

These laws are four in number. 1. Whenever the circulation is obstructed in the cranium, or in the sinuses or meningeal veins, in consequence of compression through distension of ventricles distended by serosity or any other cause, an arrest of the venous circulation occurs which produces swelling, hyperæmia, and cedema of the papilla, varicosity of the veins, and sometimes hæmorrhage in the eye. 2. When a tumour with encephalitis, or partial encephalitis, is present, a descending phlegmasia occurs which brings on sclerosis of the optic nerve, exudations which imprison the papilla, and eventually produce atrophy. 3. If it be the spinal marrow which is diseased by anterior or posterior sclerosis, since that organ, on account of its relations with the great sympathetic nerve, acts on the eye, papillary hyperæmia of the eye results, which in time brings on atrophy. This is what is seen in locomotor ataxy. 4. Finally, in all diatheses and in poisonings, when the whole organism suffers, the eye suffers like the rest of the body, and certain forms of neuritis or choroiditis result. After this preamble, M. Bouchut, by the aid of his luminous projection, showed on the wall specimens of all the ocular lesions produced by cerebro-spinal diseases. He showed the forms of spinal neuritis and those which result from locomotor ataxy, the neuritis and neuro-neuritis, produced by tuberculous, typhoid, or rheumatismal meningitis, by cerebral hæmorrhage and softening, by hydrocephalus and thrombosis of the sinuses of the dura mater, by chronic encephalitis, and encephalitis resulting from cardiac disease, by tumours of the brain, tuberculosis, syphilis, albuminuria, leucocythæmia, etc., and finally the neuritis resulting from paralysis of the sixth pair, in consequence of certain kinds of epilepsy, hallucination, contusion of the brain, etc.

In this way a hundred images were shown, the

most important of those which have been figured since M. Bouchut commenced his researches. He has thus opened a new road to the diagnosis of cerebro-spinal diseases.

ONIMUS ON TELEGRAPH CLERKS' CRAMP.—At the meeting of the French Society of Biology on March 20 (reported in the *Gazette des Hôpitaux* for March 23) M. Onimus stated that he had observed in telegraph clerks similar phenomena to those described as writers' cramp, and which the *employés* themselves have named the telegraphic disease. He gave particulars of the case of one clerk who had been employed for the last nineteen years in the telegraph office, and who began to feel symptoms of the disease ten years since. He first noticed that he could no longer clearly form the letters S, represented by three dots; I, represented by two dots; and U, represented by two dots and a stroke. He discovered at the same time that he felt a certain stiffness, a kind of cramp in the hand whilst forming these letters. The D, which is formed by a stroke followed by two dots, was much better represented than the U, which is formed inversely by two dots followed by a stroke. The clerk observing this, then tried to make use of the thumb only to write the letters telegraphically, and followed this plan successfully for two years; but at the end of that time the thumb was in its turn attacked. He then employed the middle and first fingers, but in two months they became like the thumb. He then tried the wrist, which was eventually affected in the same way as the fingers. When he endeavoured to work, the whole hand and fore-arm trembled. Sometimes he suffered from sleeplessness and a little cerebral excitement.

These accidents only occurred with the Morse instrument; and M. Onimus thinks that, if many of the *employés* are affected in a similar manner, the authorities should be asked to try some other telegraphic system.

JAMIESON ON A REMARKABLE CASE OF ASCITES.—Dr. Allan Jamieson, of Berwick-on-Tweed, relates, in the *Edinburgh Medical Journal* for April, the case of a woman who, after requiring the performance of paracentesis abdominis one hundred and thirty-three times on account of rapidly recurring ascites, made a perfect recovery. The cause of the effusion seems to have been obscure. The patient was a temperate woman, who had generally enjoyed good health, and the ascites came on gradually in 1869, her age being then sixty. She had no heart-disease, no albuminuria, never suffered from jaundice, and the size of the liver was normal, though Dr. Jamieson thinks he detected a nodular surface; the idea of ovarian disease was negated by Dr. Keith. The operations were all performed between April, 1870, and September, 1874; at one time the patient had to be tapped every week, three gallons being removed on each occasion. Towards the end of this period the fluid accumulated more slowly, but the interval between the 132nd and 133rd tapping was only three months. Since this last operation there has been no re-appearance of the dropsy; the patient now gets about actively, and is in excellent health.

SURGERY.

MANSON ON THE TREATMENT OF CONTUSIONS AND WOUNDS OF THE PERINEAL PORTION OF THE URETHRA.—Dr. Manson, in his *Thèse de Paris*, 1874, formulates the following rules for the treatment of these serious injuries, which may compromise the health of the patient after he has passed through the first symptoms. He says that, in contused wounds of the urethra, a *sonde à demeure* and perineal urethrotomy are the means to which recourse must be had. Perineal urethrotomy is principally indicated whenever the canal is destroyed to a great extent and catheterism is impossible. It should be performed with the least possible delay; and, if practicable, a *sonde à demeure* should be placed in the urethra before twenty-four hours have expired, for later on the swelling and the infiltration of urine sometimes make exploration difficult, and have thus rendered treatment unavailing. After perineal urethrotomy, keeping the penis elevated during the time the sound is left *in situ* is, Dr. Manson believes, a good means of avoiding inflammatory accidents, which for the most part are the result of the stagnation of the pus at the level of the suspensor ligament, this stagnation being in great part due to the flexion of the penis.

LABAT ON BUCCAL LIPOMA.—Dr. Labat, in his *Thèses de Paris*, 1874, has collected thirty-two cases of this affection, and has from these facts constructed a special chapter of pathology possessing great interest. These lipomata may occupy indiscriminately all points of the mouth, lips, tongue, gums, cheeks, roof of the mouth, soft palate, and palatine arch. Their essential characteristics are, to be situated directly under the mucous membrane; to form a distinct projection under it, and sometimes under the skin; and to show a transparent yellowish colour through the mucous membrane. They offer a peculiar sensation of softness to the touch, called lipomatous; thus their diagnosis is generally easy. They are easy of extirpation in consequence of their submucous situation, therefore they should be operated on through the mucous membrane, and not through the face; besides which, this proceeding presents the double advantage of rendering the operation harmless and avoiding disfigurement of the countenance.

MATERIA MEDICA AND THERAPEUTICS.

CZERNICKI ON JABORANDI AS A SIALOGOGUE.—Dr. Czernicki, in the *Gazette Hebdomadaire* of April 2, states that he had studied the effects of jaborandi on healthy subjects, and had recognised how greatly its influence as a sialogogue exceeded its sudorific power; he had always estimated the quantity of saliva secreted after a dose of five grammes at about a pint and a quarter. Circumstances gave him the opportunity of studying the therapeutic value of this remedy on several cases of mumps which occurred in the garrison of Luneville, where M. Czernicki was head of the medical staff. One of these cases was afterwards complicated with metastatic orchitis, and offered a good opportunity for making use of the action of jaborandi on the parotids to combat the metastasis. The success was complete.

The case is as follows. A brigadier, a vigorous and healthy man, was attacked by mumps on March 6. His face exhibited the characteristic disfigurement; the parotid regions were swollen, puffy, and painful; there was a moderate amount of fever, with headache and want of appetite; the mouth was dry, the saliva deficient; the movements of deglutition were painful. The general condition was good, and the patient was simply submitted to the usual dietetic and hygienic measures. On the 9th, the patient suddenly complained of an acute pain in the left testicle. On inspection the gland appeared enlarged; it was hot to the touch and very painful on pressure. Emollient applications and a laxative were ordered. The next day orchitis was perfectly established; the testicle was doubled in size and very painful. The skin was hot, the pulse rapid, and at the same time the parotid regions were manifestly reduced. An infusion of jaborandi was prescribed to be taken at once. The medicine was administered at 3 A.M. At a quarter past three, first sweating and then salivation came on, the flow of saliva into the mouth giving great relief. The salivation persisted all the morning, and the next day, when the patient was seen, he said that he felt much better, and that the testicle gave him scarcely any pain. In fact, the gland had become appreciably smaller; it could be touched and pressed without bringing on any acute pain. The parotids remained in the same condition, very little swollen and almost without pain. The patient was left quiet, without any treatment. The next day every trace of orchitis had disappeared, the swelling of the parotids had also vanished, and on the day following the patient left the infirmary perfectly cured. M. Czernicki adds that he simply relates this fact without commentary. The presence of metastatic orchitis was incontestable, and no steps were taken in regard to it before the third day, when it was well-established. The patient had neither varicocele, urethritis, nor anything which might have caused a complication;

he had never had any trouble with the testicle nor underwent any traumatism. The gland had undergone an increase to nearly double its size, and in four-and-twenty hours it regained its normal condition.

PAVESI ON THE EXTERNAL APPLICATIONS OF HYDRATE OF CHLORAL.—Dr. Carlo Pavesi, in the *Annali de Chimica (Milano)* for August, 1874, remarks that chloral was discovered in Germany by Liebig; its mode of preparation has been perfected by Dumas, Roussin, and Städeler, in France, and that it was first used as a hypnotic by Liebreich, at Berlin. It is, however, in Italy that its various antiseptic antifermentative, antiputrescent, and coagulative qualities were discovered. It is likewise in Italy that it received its first successful applications at the hands of Pavesi, Ciattiglia, Merini, and Porta. At a later period, experimentalists of all countries have borne witness to its good effects both in medicine and in surgery, and even in veterinary surgery. In Italy Signor Amici used it to preserve different kinds of vegetables, potatoes and ergot of rye, and also to destroy the itch-acarus. Prato Giurkeo used it to preserve and disinfect leeches; and many others have utilised its different properties.

Dr. Pavesi states that by continuing the researches and experiences undertaken on this head in Italy, he has kept butter for eighteen months in an atmosphere charged with chloral. With the exception of a slight odour, which, however, is not disagreeable, and disappears if the butter be washed in fresh water, it was in a perfectly sound and sweet condition. Meat and fish of all kinds, preserved for three years, lost all odour and flavour of chloral on being macerated in fresh water. After this maceration, the substances which had been submitted to these experiments regained their freshness and natural colour, and furnished products which had all the qualities requisite for good alimentation. The fibrine and the albumen were both in a perfectly satisfactory state. Dr. Cogniard, in a recent thesis on the external applications of hydrate of chloral, has made a summary of the numerous works written on this question, and does full justice to the part the Italian *savans* have had in discovering the peculiar qualities of chloral already specified.

WEIR MITCHELL ON NITRITE OF AMYL IN EPILEPSY.—The *Philadelphia Medical Times* for March 6 contains a paper by Dr. Weir Mitchell, on the use of nitrite of amyl in epilepsy, and in various other forms of spasm. He states that he has made extensive trials of this remedy during the last few years, and in April, 1872, published cases illustrating its power of arresting epileptic attacks, thus anticipating Dr. Crichton Browne's able essay on the same subject, which was published in the *West Riding Asylum Reports* for 1873. Dr. Mitchell does not think that the nitrite is capable of diminishing the frequency of the fits, but he has never known it fail to arrest an attack actually threatened when there was time to use it. Unfortunately it is only available for use by the patient in those somewhat rare cases in which the fit is preceded by a distinct aura. He directs such patients always to carry with them a phial containing a few drops of the remedy, and to inhale it freely on the first occurrence of the sensation; but in other cases, those who are familiar with the premonitory symptoms can frequently check fits when the patient himself cannot. Dr. Mitchell has

used the nitrite with more or less success in various other forms of intermittent spasm, some allied to *petit mal*, and others apparently hysterical in character. He thinks that it may also be occasionally used with advantage as an aid to diagnosis. Thus it is sometimes difficult to distinguish attacks of vertigo due merely to cerebral congestion from those due to *petit mal*; but in the one case inhalation of the nitrite will aggravate, or even produce the attacks, in the other it will give relief. In conclusion, Dr. Mitchell says that he has never met with any bad effects from the use of this remedy, though nervous patients occasionally complain of the throbbing and sense of fulness in the head which it causes.

DUCKWORTH ON THE RELIEF OF TOOTHACHE BY BICARBONATE OF SODA.—Dr. Dyce Duckworth contributes a short memorandum on this subject to the *Practitioner* (April). He was called on to treat a case of very severe toothache, and tried various ordinary remedies, including chloroform and carbolic acid, without any benefit to the patient. He then remembered having read that the pain might be relieved by holding in the mouth a solution of bicarbonate of soda. He at once gave the patient half a drachm in an ounce of water, and, to his astonishment, the pain ceased immediately, and complete relief was secured. He thinks that, as the remedy is so simple and the disease so distressing and often intractable, this treatment may be worthy of notice and of imitation.

J. W. LANGMORE, M.D.

BARNOUVIN ON THE PREPARATION OF SUPPOSITORIES.—M. Barnouvin, in the *Bulletin Général de Thérapeutique* for January 30, 1875, gives a simple and quick formula for preparing suppositories. His method is to divide the extract to be incorporated in a small quantity of lard, after having diluted it in a little water, if that be necessary, exactly as if a pomade were to be prepared; then, as the lard would have the effect of diminishing the consistence of the product, a quantity of white wax double that of the lard is added to it. The cacao butter and the wax are melted together in a porcelain capsule, after which the extract, well divided by means of the lard, is incorporated with it, by shaking it over a slow fire. The product should then be run into cardboard or paper moulds in the ordinary way. The formula for rhatany suppositories is as follows:—Extract of rhatany, 1 gramme; the smallest possible quantity of warm water; lard, 1 gramme; white wax, 2 grammes; cacao butter, 1½ gramme. This quantity is for one suppository.

DANTON ON THE PHYSIOLOGICAL ACTION OF BROMIDE OF POTASSIUM.—Dr. Danton (*Thèses de Paris*, no. 426, 1874) has based his work on M. Germain Sée's lectures and experiments. M. Sée, adopting the opinions admitted by Binz, classes bromide of potassium amongst the drugs acting on the vascular system, in the same category with ergot of rye and nicotine. M. Danton goes on to say, that bromide of potassium acts specially as a vascular medicine. It only produces any effect in the diseases held to be caused by an abnormal action of the spinal marrow or brain, by diminishing the electro-motor power and the reflex action of the nervous centres. It has that effect because it acts on the smooth fibres of the vessels, diminishes their diameter, brings on local anæmia, and in that way destroys a greater or lesser excitement result-

ing from temporary or permanent congestion. The action of bromide of potassium in epilepsy is likewise now sufficiently well proved and thoroughly demonstrated. It is, however, in cardiac affections that its best field for action is found.

PSYCHOLOGY.

KEMPSTER ON MICROSCOPICAL APPEARANCE OF THE BRAIN OF THE INSANE.—Dr. Walter Kempster, of the Northern Asylum for the Insane, Oshkosh, Wisconsin, presented to the Chicago Society of Physicians and Surgeons (*Medical Examiner*, June 15, 1874) some 'Notes on the Microscopical Appearances of the Brain of the Insane,' based on the examination of forty-nine cases. For a number of years Dr. Kempster has been making systematic microscopical study of the brain, and has examined the lesions of all forms of insanity, from acute mania to dementia, including puerperal and epileptic insanity. In each and all forms he has found a marked lesion—so that certain lesions may be grouped together as common to certain forms of insanity, to which lesions any particular type of insanity is palpably due. There is a wide difference between the lesions of acute and of chronic mania.

1. In certain forms of insanity, and notably in dementia, the finer capillaries show marked indications of disease. The perivascular sheath surrounding the vessel is distended; so much so, that sometimes the vessel itself appears to lie in a tunnel, its calibre being much less than the sheath, doubtless due to repeated capillary congestions of the vessels—often diseased—irregular in calibre, suggesting the idea of aneurismal dilations, but entirely distinct from the military aneurisms ably described by Charcot.

2. Next there is a degeneration, best studied in cases of dementia of syphilitic origin, and in the medulla oblongata, in the wall of the capillary, presenting dark-red patches at various points outside its walls, which gradually thicken, and appear to be due to a fatty metamorphosis or atheroma. The description by Meynert, though accurate, is by no means so complete as could be desired.

3. In 1871, while examining a section taken from the gray and white matter of the third left anterior convolution, there was found a peculiar appearance of the tissue. Situated in the white substance, but very closely to the gray matter, there were a number of small white spots, some round, some ovoid, clearly defined, in sharp contrast with the nerve-tissue, vary-

ing in size, from $\frac{1}{50}$ to $\frac{1}{200}$ of an inch in diameter. These appeared to be of a granular consistence, and much more dense in structure than the surrounding brain-substance; each was disconnected from the others, and normal white matter intervened. They did not absorb carmine, and were not connected with the capillaries. On the surface of some of the spots are fibres of connective tissue and crystals of margarine. To determine the true character of these spots and the degeneration, very elaborate and extensive microchemical manipulations were made. On allowing a section to dry, either with or without the nitric acid treatment, these spots appear to project above the surface of the section. By teasing, they may with difficulty be removed. None of these spots have been observed in the gray matter. They are most numerous in the medulla oblongata, and may be found in the white matter of the spinal cord.

4. There is another form of degeneracy, one which was found in the cases of acute mania. The spots are less in size; are far more numerous than in the other variety (3); resist carmine staining; do not possess the granular characteristic; there are no spindle-shaped fibres of connective tissue about them; they behave very differently under the microchemical tests applied to the other variety of spots. The points of resemblance are mainly in colour and apparent density. Neither of them have any investing membrane.

5. A fifth variety, as large in size as the third, possesses a dense investing membrane, which resists carmine staining and is less granular than the third and fourth. It exists in the same brain with the fourth variety. These spots or masses of the fifth variety are called 'colloid,' because of their resemblance to such growth, and are found in the medulla oblongata and pons Varolii. The last three varieties of degenerated masses, or spots, have one feature in common, a well-defined edge, a clean-cut margin, easily made out.

6. A sixth variety, common in cases of dementia, and where the atheromatous capillary is found, is one in which the mass passes insensibly into the surrounding normal tissue. This form is larger and less distinct than the others. It more nearly resembles normal brain-tissue. Sometimes these masses are lobulated. They are granular and dense, less numerous than in the other varieties, and do not appear in clusters. They appear to destroy or transform the tissues, and if surrounding a capillary, destroy its walls. A point of resemblance in common with the third variety is, that connective tissue fibre appears in both.

The condition of the cellular structures of the brain, of the nerve-fibres and so-called lymph-spaces, are all fields rich in results not here spoken of.

BINET ON IDIOCY AND CONSANGUINITY.—Dr. Maurice Binet asks (*Annales Médico-Psychologiques* Nov., 1874) whether consanguinity is in itself a cause of degeneration, even when the parents have all the qualities necessary for the production of healthy children, and whether the disastrous effects attributed to it are only found when the parents' health is defective. These questions are not yet solved, and for this reason he relates the history of a family in the town of Ch... (Nièvre). The father and mother are both intelligent and healthy, yet they have three idiot children. Inquiring into the family history, he found that the grandmothers of the parents were sisters married to men in no way related to them or

each other. One of these had two sons and five daughters, the other two sons and two daughters. One of the sons of the younger sister married one of the daughters of the elder; the other son married a woman not related. The father and mother of the idiots are the children of these two brothers, so that on the side of the father there are two marriages of relations, and one on that of the mother. It is said that, previously to the idiotic generation, no hereditary defect had been noticed in these families, such as epilepsy, insanity, idiocy, or scrofula; that their ancestors, both direct and collateral, were all possessed of a good constitution and intelligence; that they lived chiefly in the country, and attained an average duration of life. The father of the idiots is an only son; the mother has brothers and sisters married. Their children show no signs of idiocy. The father was, when married, twenty-six years of age, the mother, thirty. They were sober and industrious people, who made a living as hawkers. The eldest child, a boy, was born twenty-seven months after marriage, the labour being speedy and natural. The child was nursed by its mother, and was at first healthy, but when five weeks old, was attacked by vomiting and strabismus, and this occurred at intervals till his death; development was arrested, there was great weakness of the muscular system, and intelligence was absent. The child never laughed, never recognised persons, even its mother, nor cried except when in pain. It died at the age of twenty months. The second was a girl, born twenty-six months after the first. The labour was equally favourable; the child was put to a healthy wet nurse, but at five weeks old she suffered from similar vomiting and strabismus with obstinate constipation, and at the age of a year arrest of development took place chiefly in the lower limbs, which were unable to support the body. She is now two years old; intelligence is wanting and also sensibility. She hardly withdraws a limb when it is strongly pinched, and manifests no pain, and utters no cry. She is not conscious of anything cold placed on the skin. Her mother does not think her deaf, but she makes no response when spoken to. She shows no signs of intelligence, does not recognise her wet-nurse or mother; does not attempt to speak; does not attempt to take what is presented to her, and lets fall the objects which are placed in her hand. The third, a daughter, was born under similar conditions, and was nursed by the mother. At five weeks the same vomiting, constipation, and squinting appeared; and this child followed in every respect the course of the other, and has no greater intelligence. Dr. Binet thinks these facts prove conclusively that consanguinity is in itself a cause of degeneration. G. FIELDING BLANDFORD, M.D.

OPHTHALMOLOGY AND OTOLOGY.

SAMELSOHN ON AMAUROSIS AS THE RESULT OF SUDDEN CESSATION OF MENSTRUATION.—The scepticism of modern ophthalmology has thrown considerable doubt upon the many instances of amaurosis which were reported in days when the use of the ophthalmoscope was unknown, as having occurred in consequence of the sudden cessation or the suppression of some natural discharge or the disappearance of some unnatural eruption. Amongst later writers, Zehender has written as having great doubts on this point, while Von Gräfe has expressed his belief that in all other and similar cases the ophthalmoscope would have demonstrated the existence of optic neuritis. Under these circumstances the present case, which is recorded by Samelsohn (*Berliner Klinische Wochenschrift*, January 18, 1875), is of interest, inasmuch as it was marked by none of the intraocular changes which would result from any such kind of inflammation as Von Gräfe suggests.

Gertrude P., a healthy young woman, aged twenty-one, was employed, during the time of her menstruation, at some kind of out-door work which necessitated her standing barefooted in cold water. On July 30 her menstruation suddenly ceased without any pain, except that the same evening she felt a sensation of throbbing, and of pressure in the orbits; she was able to do her work the next day, but towards evening her sight was impaired, and she had difficulty in finding her way about; on the following day after some trouble she reached her village home, and applied to the village doctor, who recommended some lotion containing nitrate of silver. Soon after this she was seized with severe pain, and by the morning of August 5 she had entirely lost her sight; a lotion of belladonna was now ordered, and then she applied to Dr. Samelsohn, who examined her eyes on August 7, and found their condition as follows.

In both eyes sight was absolutely wanting; a very bright light of a lamp could not be perceived by either eye, and no phosphorence could be produced by pressure. The pupils were widely dilated and fixed; the media were clear, and in both eyes the optic disc was well defined and of a natural tint; the retina around the termination of the nerve, however, was grey and wanting in transparency, elsewhere it was apparently quite unaltered. The blood-vessels were unchanged, except that, perhaps, the veins were rather overfull. The intraocular tension was normal. The girl's general condition was good; there was no evidence of any other disease about her whatever, and, except that she was blind, her only complaint was of a dull and deep-seated pain behind the eyes. With regard to the nature and the seat of the cause of blindness, Dr. Samelsohn was strongly of opinion that, in consequence of the menstruation having abruptly ceased, vicarious hæmorrhage had occurred somewhere in the neighbourhood of the termination of the optic nerves, and not in or near the nervous centres, and that the amaurosis was the result of mechanical pressure. The prognosis was naturally grave and unsatisfactory. The treatment consisted in the use of hot footbaths with mustard cataplasms to the ankles, and the internal administration of tartar emetic. Heurteloup's leech

was applied to the left temple also. On the following day the right eye had recovered bare perception of light in the centre of the field of vision, but the left eye remained absolutely blind. The treatment was steadily continued for some days, and was rewarded by a gradual restoration of sight in both eyes, so much so that, by August 16, just ten days after its commencement, her condition was as follows. With the right eye she could read no. 1 type, and with the left eye no. 3 type; the right pupil was smaller than the left, but the ophthalmoscope could detect no structural change whatever. The patient now returned to her home, and was only seen once in the week; at the period when menstruation should again have occurred, she had severe pain in her breasts, which was relieved by appropriate treatment; menstruation recurred at proper intervals and was not again disturbed. The vision of the left eye became as completely restored as that of the right; and as the ophthalmoscope could still detect no change in the fundus, it seemed reasonable to suppose that the grey aspect and the slightly striated appearance of the retina around the optic discs were physiological peculiarities.

[On a careful review of all the circumstances attending this rather mysterious case, it is hard to believe that any inflammatory process was concerned in it, and the evidence is strongly in favour of the occurrence of hæmorrhage, and this too in the orbits rather than within the skull; on any other supposition the nature of the case can hardly be explained, although from any point of view Dr. Samelsohn has done well to place so interesting an occurrence upon record.—*Rep.*]

GUYE ON THE INFLUENCE OF COLD AND SEA-BATHS ON THE ORGAN OF HEARING.—The direct effect of cold is best observed in cases in which cold water has run into the ear during a bath, and in consequence of which an acute inflammation is excited. At the last meeting of the Association of Naturalists and Physicians, Dr. Guye, of Amsterdam, mentioned two cases illustrating this point, both of which recovered after paracentesis of the membrana tympani and other subsequent treatment. The *Allgemeine Wiener Med. Zeitung*, January 19, 1875, gives an abstract of Dr. Guye's remarks. The injurious effects of cold are also observed when the patient has attacks of giddiness in consequence of cold injections into the ears; if warmer water be then substituted, there will be no return of the attacks. The opinions of aurists relative to sea-baths are very diverse. A few consider them injurious, and others useful. Dr. Guye believes that he has solved this question, and lays down the rule for the diagnosis of the cases in which sea-baths are indicated, from those in which they must be looked upon as injurious. In one class of cases he has found sea-baths not only void of danger, but of the greatest utility; in another series, they have either aggravated the existing aural complaint or have occasioned the first symptoms of a new one. He considers the difference to lie in the fact that the attacks of dizziness which indicate labyrinthal disturbances are always absent in the former class, while, on the contrary, they are certainly present in the latter. Dr. Guye thinks, therefore, that such cases in which symptoms of disease in the labyrinth are already present, or in which there may be a predisposition to them (especially if it be a hereditary predisposition) contraindicates the employment of sea-baths; but that in all other cases

(the necessary precautions being of course taken) they may be resorted to without danger.

BOWATER J. VERNON.

KNAPP AND OTHERS ON OPHTHALMIC TUMOURS. In vol. iv. no. 1 of the *Archives of Ophthalmology and Otology*, Messrs. Knapp, Turnbull, Thompson, and Williams report several cases of ophthalmic tumours which are in some respects worthy of note.

In one case of glioma of the retina, occurring in a girl three years of age, there were numerous 'metastatic' tumours found on the cranium directly over the sutures, and others on the inferior maxilla and neck. These swellings are described as 'subcutaneous, immovable, and sharply defined intumescences.' About two months after the eye was extirpated, the child suffered from a succession of tetanic convulsions, which was attended with a shrinking of the larger tumours, disappearance of the smaller cranial ones, and an improvement of the child's health for several days. The child died some days afterwards, seemingly of exhaustion, and a *post mortem* examination revealed the sutures of the skull as raised, and marked by red lines, which, after incision of the pericranium, proved to be areolar tissue saturated with blood. On the outer surface of the skull round tumours were observed, which showed connection both with the pericranium and bone, the surface of the latter being rough and corroded. 'The substance of these tumours was finely granular, with some very red and soft fibrous stripes.' The skull was of ordinary thickness, its inner surface showing numerous small depressions, surrounded by a wall of very vascular osteophytic excrescences; and corresponding to these depressions were soft red tumours, situated on the outer surface of the dura mater. The microscopic examination in all the tumours gave the gliomatous or encephaloid cancerous structure. In commenting on this case, the reporter points out that it differs from the few cases of glioma metastases on record, in that the metastatic tumours originated between the periosteum and the surface of the bone, and not in the diploë, and that here in some places intracranial tumours corresponded to extracranial ones, the diploë between them being but little changed.

In another case of glioma, the family predisposition to this affection was remarkable. The right eye was the one affected in the patient, a girl aged twelve months. The history of the family shows that a brother of this child had been 'similarly diseased' at two years of age, and died eleven months after the affection had been first observed. A cousin of the patient on the father's side was attacked in the left eye in his second year, and died a few months after it was first noticed. The father's aunt lost two children between two and four years old, whose eyes were said to be diseased in exactly the same manner. 'In no case has any relative had any cancerous disease in any other organ or tissue, to their knowledge.' On examination of the eye after enucleation, the smallest tumours showed with the greatest distinctness that the pseudoplasm originated in the inner granular layer.

In a case of melano-sarcoma, the microscopic examination of which was made by Professor Knapp, a new feature of propagation of intraocular sarcoma is mentioned, viz., 'the occurrence of secondary tumours by dissemination of germs from a remote tissue,' in the same way that glioma of the retina extends to the choroid.

Another case of intraocular melano-sarcoma occurred in a tuberculous girl, twelve years of age. During the early development of the growth, which originated in the vicinity of the optic disc, and extended by propagation, there was no pain, nor did pain occur till eighteen months after it was accidentally discovered that the eye was blind.

SCHOEN ON PERCEPTION OF COLOUR.—In the *Berliner Klinische Wochenschrift* for July 20, 1874, Dr. Wilhelm Schoen, of Leipzig, gives the following as the result he has obtained from his investigations on colour-blindness. Should a peripheral nerve-fibre have its perception of light lowered to a quantity x , its neighbouring bulb still reacts to an influence from green, but should the perception sink to x and y , green will no longer be perceived. Should the perception be further lowered to x , y , and z , the perception of red also ceases; that is, the excitability is so much lowered, that no waves of red light can cause irritation of the elements which perceive red; while, should a further degeneration take place, the perception of blue is also lost. In other words, an irritation of slight intensity suffices to call forth the perception of blue, a stronger is required for red, and it is necessary to have a yet stronger for green. He says he has often observed that a patient with atrophy of the optic nerve appears blind for a certain colour till the light has been increased, and that a small coloured square was not recognised, while a square of larger surface of the same colour was rightly determined. The disturbances of colour caused by the administration of santonin are, he thinks, explained by the increased circulation and the accordingly increased change of tissue, an increased hyperæmia of the retina, the arteries and veins of which are both enlarged in calibre, being visible by the ophthalmoscope. This explanation suffices also for the symptoms of delirium and hallucinations which are seen after the administration of santonin in full doses. Dr. Schoen believes that santonin has in his hands been of much benefit in cases of amblyopia, arising from the excessive use of tobacco or intoxicating liquors, and in the commencement of atrophy from exhausting discharges; while in amblyopias with increased fulness of the vessels, especially of those in the neighbourhood of the macula lutea, nothing is to be hoped for from its use. He gives from three to seven grains of the santonate of soda as a dose, which generally causes a moderate yellow colour to be present. Large doses of the preparation cause paralysis of the retina.

KÖPPE ON REFLEX MENTAL AFFECTIONS AFTER EAR-DISEASES.—Professor Köppe relates, in the *Archiv für Ohrenheilkunde* for the 8th ultimo, two cases of mental affection after disease of the ear, which have come before him at the asylum at Halle, of which he is director. Quoting Hitzig's statement that any considerable injuries to the nervous system, whether they have a central or a peripheral seat, can bring the whole system into sympathy, he thinks that the lesion of certain regions can more easily cause central functional derangements than the lesion of others, and finds that in the cases collected by himself injuries to the region of distribution of the sensory branches of the fifth nerve are more important than injuries to any other region. The two cases referred to are brought forward in support of this statement.

In his concluding remarks, he mentions that the

form of the auricle depends greatly upon the cranial development, and says that he has repeatedly found peculiar forms of cranium and auricle combined in blood-relations who have suffered from mental and aural disease. He believes with Tröltzsch, that family dispositions to ear-affections are grounded upon similarities in the formation of the bony ear, and that these, again, are referable to similarities in the form of cranium.

The treatment of the ear-affections alone was, in both cases, followed by the complete removal of the mental affections, on account of which they had been placed under Professor Köppe's care.

W. LAIDLAW PURVES.

BARBER ON IODOFORM IN GRANULAR LIDS.—Dr. Barber, who practises in Saginaw City, Michigan, communicates his experience of treating granular lids with iodoform to the *Detroit Review of Medicine*. in the amusingly free and easy manner peculiar to our Transatlantic brethren. He writes as follows to the editors.

'Without going into any "profound analysis of the subject," allow me to tell you what I know of treating granular sore eyes with iodoform. Some time ago I had a patient who had suffered much from many physicians (myself included.) He was a sneaking, sniveling son of a gun, and would come sidling into the office with a drooping, mournful expression in his large, sore eyes that was truly aggravating. Months passed by, and still my sore-eyed friend haunted my office with such punctuality and pertinacity that I resolved to cure those eyes or die. I brushed them with all the remedies known to modern oculistic surgery, and floated his intestinal apparatus in a sea of tonics and alteratives; and when all these things had failed, I used to take him around to medical societies as a sort of permanent clinique, and then to my office and try the suggestions; but the patient grew worse gradually, and so did I. Finally, in a medical journal I saw an account of the successful treatment of an intractable ulcer of the leg with iodoform, and the idea suggested itself that it might be "good for sore eyes," and I had twenty grains put in an ounce of glycerine, and applied some to the inner surface of the lids, and in came the patient next day, with a sweet smile and a whitening cornea, and I felt "as if my life's work was ended"—that I could "step down and out." The patient got well without a drawback in a short time, and I have tried the remedy in quite a number of cases since with very gratifying results.'

TOXICOLOGY.

SCHUMACHER AND SPANGLER ON A CASE OF POISONING BY NITRO-BENZOL [ESSENCE OF MIRBANE].—The subjoined case is detailed at considerable length in no. 12, of the *Wiener Medizinische Wochenschrift* for 1875. Seven weeks before the accident, the ingredients for a liqueur were purchased by the sister of the deceased. The receipt was nearly as follows: 18 pints of water, 5 pints of rectified spirit, 8*d.* worth of syrup, 1*d.* worth of colouring, 8*d.* worth of essence of almonds; some sugar and peppermints were added; and the whole digested fourteen days. Two or three people had taken some of it, and did not like it. On January 13, the remainder was poured into a jar, about three tablespoonfuls being left behind in the original flask. A little brother of the maker, aged seven, who had several times drank as much as three wineglassfuls of the liqueur, came from school about 2.15, and begged for this remainder. His sister poured it into a glass; he drank it, ate some bread and butter, drank some butter-milk, went off to slide, and returned at quarter to 5 P.M. He soon vomited, and lay down on a settle; only two little sisters being then at home. The vomit smelt strongly of bitter almonds. The elder sister returning, found him with a fixed stare, groaning, and speechless (he never spoke again). She fetched a midwife, who gave him new milk, and applied cold to his temples. A surgeon saw him, and is said to have given an emetic, and some medicine, taken home by a brother in the evening. The medicine had no effect, and he died at 12.30 (midnight). The remainder of the liqueur was thrown away. However, the policeman took with him the little bottle which had contained the 'almond-essence.' There was no suspicion of any other poison being taken. Neither this child nor the others had suffered from the previous draughts. It was noticed that the last of the liqueur was thicker than before, and it was never shaken before being poured out. On the 16th, at the *post mortem* examination, the pupils were found dilated: there was moderate cadaveric rigidity. There were numerous bright red spots on the posterior parts of the body (hypostases). The smell of bitter almonds was very evident on opening the skull, also in the blood in the heart, and in the contents of the stomach and intestines. There was general congestion of nearly all the organs of the body; also punctiform ecchymoses in the brain, pleuræ, lungs, mucous membrane of stomach and intestines, etc. The right heart was full of dark thin venous blood; there was a large fibrinous concretion in the left ventricle. The lungs were rosy red, with darker ecchymoses. There were no other special appearances.

As only a drop or so of the essence was left, it was necessary to find tests to distinguish true essence of almonds (*Bitter-Mandel Oel-Ether*) from the spurious, or nitro-benzol. The following were found on trial. 1. True essence of bitter almonds, containing hydrocyanic acid, easily dissolves in 200 parts of water. 2. One half of this solution, treated with alcohol and ammonio-nitrate of silver, gives a precipitate of cyanide of silver on adding nitric acid. 3. Caustic soda when added to the other half, with a salt of iron, gives Prussian blue on the addition of hydrochloric acid. 4. Genuine natural ethereal (or essential) oil of bitter almonds treated with hydrochloric acid, dilute sulphuric acid, alcohol, ether, and zinc is deoxidised, and hydrogen is generated. The product of this on neutralising the acids with caustic soda, and shaking with ether, gives, on drying in a water-bath, a thick yellow fluid residuum, which does not change colour with solution of chlorinated lime. 5. The genuine essence mixed with alcohol placed in a dry saucer, on the addition of a bit of bright fresh dry metallic sodium, bubbles at first, with a pale yellow froth, which finally turns a bright red. On the other hand, genuine nitro-benzol is (1) almost insoluble in water, only slightly soluble in alcohol, gives no reaction with tests (2) and (3), but in (4), chlorinated lime gives an intense bluish-violet coloration (due to development of anilin); with (5) there is a dark-brown foam. The application of these tests to these remains of the essence, and of the liquid drank, showed conclusively that they consisted of pure nitro-benzol—a deadly poison. The authors remark that the suddenly fatal course of the symptoms, the thinning and dark coloration of the blood [rapidly changing to a brighter hue on exposure to air], and the *post mortem* appearances, point to decomposition of the blood by the poison. That this was really the cause of death is evident from the inspection, as there were no signs of any previous disease, and he is known to have been in good health previously. It is not known what is the smallest fatal dose. The boy probably took nearly all that was purchased. Only a few drops remained in the half-ounce phial which originally held the spurious essence of almonds. [There is reason to fear that nitro-benzol, or essence of mirbane, is often sold in England for essence of almonds. The following are additional points of distinction. The genuine essential oil of almonds has a specific gravity of 1.064, whilst it boils at 179.5° Cent.; it is soluble in thirty parts of cold water, and in almost all proportions in alcohol and ether. Nitro-benzol, or the spurious essence, has a specific gravity of 1.209; its boiling-point is about 220° Cent. Besides the tests mentioned above, other reducing agents, as sulphide of ammonium, zinc and hydrochloric acid, iron filings and acetic acid, etc., will develop aniline, which colours solution of chlorinated lime an intense violet-blue. Chromate of potash and sulphuric acid also colour it blue.—*Rep.*]

W. BATHURST WOODMAN, M.D.

JÄDERHOLM ON THE MEDICO-LEGAL DIAGNOSIS OF POISONING BY CARBONIC OXIDE.—Jäderholm (*Nordiskt Medicinskt Arkiv*, vol. vi. nos. 11 and 21) says that the most certain means for detecting this form of poisoning will always be the actual demonstration of the poisonous gas in the blood. To this end, three methods have been proposed, viz.: (1) The spectroscopic examination of the blood; (2) the reaction with caustic soda; and (3) 'aspiration,'

with the reaction by chloride of palladium (Eulenburg).

To test these methods, and especially to determine how long after death they are still applicable, the author killed several small dogs and rabbits by carbonic oxide, either pure or in the form of coal-gas, and examined the bodies either immediately or at various intervals (up to one or more months) after death; the blood being in some cases exposed to the air, in others contained in closed vessels, and either pure or mixed with solution of borax, which has no effect on the spectroscopic characters. When secluded from the air, the blood showed the spectroscopic reaction due to carbonic oxide, even four or five months after death; but, if it be exposed to the air, the gas soon escapes.

With regard to the spectroscopic results, the author notices the following points. The absorption-band of reduced hæmoglobin does not occur precisely between the two bands of oxyhæmoglobin, since the absorption of hæmoglobin extends further towards the red after reduction than before; which is important when the reduction is (as it always is in this case) partial. The author prefers, as a reducing agent, the alkaline solution of ferrous tartrate used by Stokes. He has attempted to ascertain the precise position of the absorption-bands, and finds that the middle of the band α in ordinary blood corresponds to a wave-length of 5730, the middle of β to 5370. In blood affected by carbonic oxide, the middle wave-length of α is 5690, and of β 5340.

The reaction of blood with caustic soda, proposed by Hoppe-Seyler, is also valuable. Ordinary blood, shaken up with this reagent, gives a brownish-green precipitate, and carbonic oxide-blood a red compound; but both pass, after a time, into red solutions, similar in appearance, but giving different spectroscopic reactions. In the red solution thus obtained from normal blood, hæmoglobin is transformed into reduced hæmatin (of Stokes), while in the carbonic blood the colour is due to the presence of a combination of carbonic acid with hæmatin or carbonic oxide hæmatin, the existence of which has been already pointed out by Popoff, though reduced hæmatin is also present. The spectrum of this solution is accordingly compounded of the spectrum of reduced hæmatin and that of carbonic oxide hæmatin. The spectrum of carbonic oxide hæmatin itself resembles that of oxygenated or carbonic oxide blood; but the two absorption-bands are paler and nearly equal in strength. The red liquid called by Hoppe-Seyler 'hæmochromogene,' prepared by adding (without access of air) caustic soda to a solution of hæmoglobin already reduced by hydrogen, may be shown, the author says, to be nothing but Stokes's reduced hæmatin in alkaline solution.

Jäderholm cannot confirm the statement of Eulenburg and Vohl, that ferricyanide of potassium is a specific re-agent for carbonic oxide blood; nor has he obtained satisfactory results from Eulenburg's method of aspiration.

REVIEWS.

Die Carbolsäure in der Medicin. Von C. G. ROTHE, Altenburg, p. 63. Berlin: A. Hirschwald, 1875.

[*Carbolic Acid in Medicine.* By C. G. ROTHE, of Altenburg. Berlin: Hirschwald, 1875.]

This is a reprint of a paper read at a medical society. The introduction is eminently German. The author begins by denouncing all 'mysteries,' and all believers in 'shock' or 'dynamic potencies,' as either homœopaths, 'ladies of one or other sex,' or country clergymen. He then very candidly, though inconsistently, admits that the real action of carbolic acid, in fatal doses, is as great a mystery ['selbst ist so wenig aufgeklärt'] as that of strychnine, hydrocyanic acid, or morphia. He holds, however, that carbolic acid has, in proportion to the dose, a killing or destructive effect upon all kinds of life, animal and vegetable—or, to use his own words, it is 'ein Gift für alle Organismen.' The word 'organisms' appears, like Mesopotamia to Mr. Whitfield's convert, to have a very soothing effect upon Dr. Rothe's mind, as he repeats it frequently, evidently with much mental satisfaction. There is little, if any, novelty in the pamphlet; but it is a fair *résumé* of the surgical and medical applications of this acid. French and English authorities scarcely get their fair share of quotation or credit; for example, Dr. Sansom's 'antiseptic system' appears to have been very freely made use of, whilst his name is quoted only casually, as if he had merely used the sulpho-carbolates once or so. After some description of carbolic acid, its physical and chemical properties, etc., the surgical applications are described, its use in 'Lister's' method for operations, wounds, frost-bites, burns, ulcers, carbuncles, etc., and as a vesicating agent; the author then begins at p. 18 to treat of its uses in medicine. He commends its use in the form of inhalations in phthisis, and gives the following formula: R. Carbolic acid in crystals, and spirits of wine, of each two parts; tincture of iodine, one part; distilled water, ten parts. Mix. Twenty-five to thirty drops to be added to one or two tablespoonfuls of water, for inhalation. He uses the same solution for diphtheria, to paint the tonsils, pharynx, etc. An Italian chemist, Enrico Savoli ['L'Idro-Alcoolato de Ioduro di Fenile, ovvero Micela antidifteritica,' etc. Milano, 1872] reports the signal success of this treatment in an epidemic in Milan. Dr. Rothe recommends it also in catarrhal angina, and catarrhal affections of the loci; also in hooping-cough, combined with belladonna and syrup of poppies; in diarrhœa, dysentery, and summer cholera. He speaks doubtfully of the success in zymotic diseases (scarlatina, typhoid fever, etc.), syphilis, and even cutaneous parasitic diseases; more hopefully of its employment in certain cases of diabetes mellitus, of which little need be said, as Ebstein and Müller's trials of this remedy have been pretty fully reported in our pages. The author concludes with the following peroration. 'The tendency of the medicine of today is to go straight to the root of every disease. And if the progress of discovery succeeds—as Dr. C. Stropp (in his 'Vaccination and Micrococci,' Berlin, 1874) confidently predicts, and the genial researches of Hallier are showing us the road already—in finding out a specific fungus for every

infectious disease, hygiene and therapeutics will not be backward in laying a solid "mechanical" basis by the further development of antiparasitic methods of treatment !'

W. BATHURST WOODMAN, M.D.

On the Force used in Transfusion, and on the Selection of Fluids for Injecting into the Veins. By W. W. WAGSTAFFE, F.R.C.S., Assistant-Surgeon to St. Thomas's Hospital.

This is a reprint of a paper which appeared in the *Obstetrical Journal* for December, 1874. It may fairly be considered a practical contribution to the subject of transfusion. The details of two cases are given. In one the transfused fluid was milk, and in the other milk with an equal quantity of defibrinated blood. In the latter the patient was too far gone from the combined effects of shock and hæmorrhage to be benefited by the operation—there was no response to the transfusion. In the former, the patient had had both legs amputated and had lost a good deal of blood. A pint and a-half of milk (made from the condensed form) was transfused. The immediate effect was to rally the patient and raise the temperature two to three degrees; but shortly afterwards she began to sink, and died a few hours after the transfusion. Both cases, therefore, terminated fatally. Milk as a substitute for blood in transfusion has still to be put on its trial. The idea is not new. On the contrary, it has been often suggested, and cases have been mentioned from time to time in the American papers—not, however, with sufficient detail as to the immediate and remote effects to make them of much value. As the plan must still be considered an experimental one, perhaps it would be better that the experiments should first be made on some of the lower animals—such as cats or dogs. This is one of the points which is engaging the attention of the Committee on Transfusion appointed by the Obstetrical Society, and will, no doubt, be tested by experiment. It would certainly be a great advantage to be able to use such a readily obtainable fluid as milk in transfusion; but it must be remembered that the blood in the veins is a very complex vital fluid, and it takes very little to damage its integrity. It is, however, a fact worth remembering, that Mr. Wagstaffe's patient lived six hours after having had a pint and a-half of milk injected into her veins, and that death was probably caused by the double shock of the injury and the amputations. The instrument used by Mr. Wagstaffe seems to have been effective in his hands. It is really a return to the old plan, modified and improved, introduced by Dr. Hamilton, of Ayr. This plan was simply a funnel with about two feet of tubing attached to it, the weight of the blood being supposed to be sufficient to force it into the vein. Most experimenters, however, have found this force, the force of gravitation, insufficient, and hence a great variety of instruments have been invented to overcome the difficulty.

Mr. Wagstaffe's experience in this respect differs from that of many others, for he was able to inject without difficulty a large quantity (possibly too large) of milk. He also claims for his instrument (of which a drawing is given) that it admits of a suction-power in the vein by which the blood, or whatever fluid is used, is drawn or received into the system in a more natural and safe manner than when force of any kind is employed. HENRY M. MADGE, M.D.

Tables of Materia Medica.

This small pamphlet will certainly be a welcome and useful book to students and practitioners, for it comprises the contents, doses, proportion of active ingredients and methods of making the various pharmacopœial preparations, arranged in a tabular form and grouped together in such a way as greatly to aid the memory. The preparation of an alkaloid, for example, is divided into its chief stages, and under these headings are arranged the processes necessary in each, so that the student may easily see their use. The extracts, powders, pills, tinctures, etc., are grouped according to their doses, so that, instead of having to get up the dose of each separately, most of them can be remembered as belonging to a particular group. This useful little work is printed by Walter Hawkins, 3 Albert Terrace, Bishop's Road, W. It does not bear a publisher's name, but may, it is said, be obtained at the various hospitals. T. LAUDER BRUNTON, M.D.

MISCELLANY.

THE fourth session of the German Surgical Association was held last week in Berlin, under the presidency of Professor von Langenbeck.

MR. A. H. GARROD, of King's College, Cambridge, has been appointed Fullerian Professor of Physiology to the Royal Institution for the next three years.

A NEW MEANS OF IDENTIFICATION.—Mr. W. B. Woodbury recommends that for purposes of identification (of criminals, for example) it is only necessary to get a distinct photograph of the palm of one hand, taken in a strong oblique light, so as to bring out the markings strongly. This will be found a map, he says, never alike in two persons; no disguise short of actual disfigurement can do away with the difference.

THE Clothworkers' Company have founded in King's College, London, one annual exhibition of 25*l.* for two years for proficiency in science, open not only to actual students of the college, but to all under nineteen years of age who are intending to devote themselves to the study of mathematics, mechanics, physics, chemistry, botany, and zoology. Each candidate may select any four of these subjects.

TOBACCO SMOKE.—Dr. Otto Krause, of Annaberg, has been making researches into the composition of tobacco smoke, which are published in *Dingler's Polytech. Journal*. He finds that tobacco smoke contains constantly a considerable quantity of carbonic oxide. The after effects of smoking are said to be principally caused by this gas, as the smoker never can prevent a part of the smoke from descending to the lungs, and thus the poisoning is unavoidable. The author is of opinion that the after-effects are all the more energetic the more inexperienced the smoker is; and he thus explains the unpleasant results of the first attempts at smoking, which are generally ascribed to nicotine alone.

THE EFFECT OF EMOTION.—It is related by Kurt Sprengel (*Geschichte der Arzneikunde*, vol. ii. p. 371) that the Arabian physicians sometimes relied with great success on moral means, of which the following is a striking instance. One of Haroun Al-Raschid's wives suffered from paralysis of both arms. Dschibrail, the court physician, induced the caliph to summon all the leading nobles to a large hall in his palace, and then introduced the lady to the assembled multitude. Without a word of preface he raised her veil, when feelings of shame and fear restored strength to the palsied arms. The lady hastily drew her veil down again, and was cured from that hour.

TELEGRAPH CLERKS' CRAMP.—With regard to this new form of disease, which was reported by M. Onimus to the French Society of Biology, it may be noted that it only occurred in cases where the Morse instrument was used. M. Onimus remarked that, should other *employés* be attacked with this unpleasant product of modern civilisation, it would be advisable to introduce the use of Hughes's instrument.

HOW TO SAVE TROUBLE.—Dr. John C. Peters, in his address on 'Sects in Medicine,' delivered before the New York Medico-Legal Society, says: 'The Tartar physicians, or Llama doctors, have long superseded infinitesimal doses, as, if they do not happen to have any medicine with them, they are by no means disconcerted, for they merely write the name of the remedy they wish to give on a little scrap of paper, moisten this with the saliva, roll it up into a pill, which the patient tosses down his throat with the same perfect confidence as he would aloes, assafoetida, or any other remedy. To swallow the name of the remedy, or to take the medicine itself, say the Tartar physicians, by any patient, comes to precisely the same thing. If paper is not at hand, the name of the drug is written with clay or chalk upon a board, which is then washed off, and the patient swallows the liquid.'

MEDICAL EDUCATION IN SWEDEN.—Stockholm possesses a fine school of medicine, with a remarkably well-arranged museum of pathological anatomy, and a fine anthropological museum. Besides this school at Stockholm, there are two faculties of medicine, which form part of the universities of Upsala and Lund; the first founded in 1477, the second in 1688. Instruction in these faculties is absolutely free and gratuitous. The student may attend all the courses he wishes, without paying any fees, always provided that he has passed a satisfactory examination on leaving one of the upper elementary Swedish schools. The faculty examinations give in succession the titles of candidate, licentiate, and doctor. A recent law allows women to apply for the doctor's degree. The professors are divided into three categories—the professors properly so styled, the assistant-professors, and the *agregés*. The professors at class receive 4,500 rixdollars, or about 800*l.*, a year, and the assistant-professors about 400*l.*, and the *agregés* do not receive any remuneration. In 1873, there were 168 professors of all grades, in the Swedish universities, and 2,080 students. Upsala possesses 250 scholarships, and Lund 200; each scholarship being worth from 20*l.* to 50*l.* per annum. Finally, some prizes of 20*l.* and upwards are distributed at the examinations for travels for scientific purposes. The expenses of the universities are partly covered by the revenues of their large domains, partly by the state. In 1870, the state contributed 1,758,587 rixdollars to Upsala, and 1,037,232 rixdollars to Lund.

INTERNATIONAL MEDICAL CONGRESS AT BRUSSELS, 1875.—The fourth session of the periodical International Congress of Medical Science will commence at Brussels on September 19, 1875, and will last a week. It will be composed of those native and foreign medical men who send in their names to the committee, and who alone will have the right of taking part in the discussions. The only expense incurred by members will be 12½ francs (10*s.* 6*d.*) for a copy of the report of the proceedings of the session. A card of admission will be forwarded with the receipt for this subscription. Applications for admission are to be made on and after July 1, and members' names will be forwarded and cards of membership distributed on the afternoon of September 18, and the morning of the 19th. Members must have their names put down in the section to which they desire to belong. A member may belong to several sections. The congress will meet twice daily; in the morning for the work of the sections, and to reading the reports of the sections and discussion of their contents. Members wishing to read papers on any subject not

included in the programme, must give notice to the committee at least a month before the opening of the congress. No one will be allowed to speak more than twenty minutes; this restriction, however, does not extend to the sectional reporters. All papers read at the congress must be left at the committee room for publication at the discretion of the committee. The proceedings will generally be conducted in the French language, but foreign members will be allowed to express themselves in their native tongue. If wished, the sense of their discourses will be briefly interpreted to the meeting. The committee consists of M. Vleminckx, president; and MM. Deroubaix, Bellefroid, and Crocq, members; with M. Warlomont, general secretary, to whom all communications relating to the congress should be addressed. The programme of the congress is as follows. 1. *Medicine* (comprising pathology, pathological anatomy, and therapeutics): the prophylaxis of cholera; alcohol in therapeutics; the inoculability of tubercle. 2. *Surgery* (comprising military surgery and syphilography): on surgical anæsthesia; and the dressing of wounds after operation. 3. *Obstetrics* (including diseases of women and children): lying-in hospitals. 4. *Biological Science* (comprising anatomy, physiology, comparative medicine): the vaso-motor nerves and their mode of action; the value of experiments based on artificial circulation. 5. *Public Medicine* (comprising hygiene, forensic medicine, medical statistics): the means of making workshops healthy in which phosphorus is manipulated; the organisation of the public health service; the manufacture of beer. 6. *Ophthalmology*: defects of vision in relation to the military service. 7. *Otology*: the means of measuring hearing and registering in a uniform manner in all countries; defects of hearing in relation to the military service. 8. *Pharmacology*: should the medical employment of chemically defined principles immediately be extended, and should the preparations of them be multiplied in the pharmacopœias? the establishment of an universal pharmacopœia.

'PERFECT DAYLIGHT!'—All persons desiring to improve the lighting of their premises or apartments may easily do so by availing themselves of that most useful of modern inventions, 'Chappuis' Patent Daylight Reflectors.' They can be adapted to any window, skylight, etc. The manufactory is at 69 Fleet Street London.—[ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 1*7s.* 4*d.*; free by post, 1*9s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 1*9s.* 6*d.* Cloth Cases for binding the Numbers for each year may be had for 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, APRIL 21, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

YEO ON THE PROGRESS OF KNOWLEDGE CONCERNING CANCER.

Dr. Gerald F. Yeo publishes a valuable review of the subject in the *Irish Hospital Gazette*.—The word tumour is now used in a much more restricted sense than is really conveyed by its original meaning, as it is generally applied to such swellings only as are permanent. Some writers call many kinds of fluid collections tumours, while others restrict the term to growths of new tissue. Even this definite but narrow view of the word often leads to difficulty in deciding whether a given swelling deserves the name or not; for it is by no means easy to draw a line between some forms of hypertrophy or hyperplasia, and an enlargement which no one would hesitate to call a neoplasm.

Without going into the question, what is a tumour, let us pass to that which every practical man is tempted to ask when he sees a swelling of any kind, namely, Is it malignant? The surgeon, after his operation, anxiously puts this question to the pathological anatomist, who often can give him only an insufficient answer, as the latter is in the habit of viewing tumours from quite a different standpoint, and makes use of a nomenclature, the very terms of which are strange to the practical man, or if they be familiar, they convey a very different meaning to his mind from that given to them by the pathologist. The fact is, the question, Is it malignant? is purely a clinical one, malignancy expressing a clinical idea that springs from the tendency to destroy life, which exists in a greater or less degree in most tumours, but is fortunately wanting in some few. It is a mere relative term depending upon a number of circumstances, of which structural peculiarity is far from being the foremost.

Some surgeons who see that malignancy must depend more upon clinical than on structural characters, substitute the question—Is it a cancer? But this question is equally hard for a histologist to answer, from the want of an adequate definition of the word. An author writing forty years ago says: 'Although the term cancer possess but little etymological recommendation, the moderns, enlightened as they are by pathological anatomy, employ it with a far more precise and settled meaning than the ancients.' (Cooper's *Surgical Dictionary*, 1838, p. 117.) Can we say this with truth now, when no later than last year, in the discussion of the London Pathological Society—a discussion of which England ought to be proud, thought their President—we find eminent authorities differing materially as to the meaning of the word? (*British Medical Journal*, 1874.) Mr. J. Hutchinson 'protests against the right of modern histologists to give a new meaning to the word cancer;' and Mr. Simon 'wishes to keep the con-

venient word to mean not only various forms of carcinoma, but also sarcoma and glioma.' Cancer is then also alleged by surgeons to be a term expressive of a clinical idea, and appears synonymous with the vague word, malignant tumour. Pathological anatomists ought then to give up the exclusive right of using the word to the practical surgeon who may employ it, either with its ancient and original meaning, namely, a swelling with superficial veins resembling the claws of a crab, or with a more recent practical one, restricting it to carcinoma, sarcoma, and other malignant growths.

The want of a definite and general nomenclature no doubt leads to much confusion; and this confusion must always exist while clinical observers persist in dividing tumours into benign and malignant; or, in other words, arranging them according to the results they may produce on the general system instead of their individual characters. Surely as products of nature, they have a right to some form of classification, founded on their nature and anatomical peculiarities; and when they are so arranged, the various influences exerted by each class upon distant parts of the organism may be more reasonably studied.

As Virchow says (*Onkologie*), pathological anatomy must be treated in the same manner as other branches of natural science. Thus in botany it is no doubt very useful to arrange such plants as are edible or poisonous into two distinct classes, but no one dreams of adhering to such a division to the exclusion of their botanical characters. Such qualities would form a very bad groundwork for scientific classification; for different plants of the same species, or even different parts of the same plant, possess properties which vary much in this respect. Or it may be very interesting, from an ecclesiastical point of view, to divide all men into the good and the bad ones. It would be frequently hard to draw the line between the two, and the degrees of such a distinction would hardly satisfy an anthropologist as adequate characteristics of the various races. So it may be practically convenient to the surgeon to call a certain kind of tumour 'lupus,' but the structure and genetic relations of this wolf of the tissues may differ widely from many others which share its preying propensities.

Of course it is of the greatest importance to study the degree of malignity belonging to each kind of tumour; but it is of much greater importance for pathology, at the present state of our knowledge, first of all to have a definite classification founded on anatomical and histogenetic grounds. In zoology, when a good anatomical classification of animals has been fixed upon, the beasts of prey may be separated from the others, and called a group.

The malignancy, then, of a given tumour ought not to be decided upon until: 1, the class to which it belongs; 2, its anatomical relations; 3, its history; and 4, the vigour of the patient, have been carefully considered.

We find it necessary to use the word cancer in order to give the meaning of some authors; but we wish it to be understood that we do so not in the sense of malignant growth, but in the histological sense, namely, carcinoma or epithelioma, that is to say, containing cells of an epithelial type. Although many of the most malignant growths do not belong to this category, it may be taken as the most surely destructive form of tumour; and perhaps a brief analysis of the steps of progress which have been

made of late years in the study of its structure and development may be interesting.

After Joh. Müller (*Krankhafte Geschwulste*) had applied Schwann's theory of the free development of cell-elements in structureless blastema to the explanation of the formation of pathological growths, he gave the first accurate description of the structure of tumours, but he still adhered to the division into two great groups, 'benign' and 'malignant.' At the same time, however, he distinctly stated that the structural elements of carcinoma differed in no essential point from those of benign tumours, and that the tissue of every tumour had its representative in the normal tissues at some period of the development of the body. In spite of this, which may be considered to be the first great rule in the histology of tumours, the specific cancer-cell, as subsequently described by Lebert, was eagerly clung to as a convenient sign-board of malignancy, and Müller's law was not recognised till long after Virchow had insisted on the facts, that not only each cell in a tumour had its equivalent in the normal tissues, but that it also was the direct descendant of a pre-existing cell, which for him was the connective tissue corpuscle. Thus, the 'cancer-cell' came into disrepute, and pathologists were forced to look to the structural arrangement and the development of a tumour, rather than any specific element, in order to determine its true nature and rank in a scientific classification.

The mode of cell-development, as propounded by Schwann, and accepted by Müller, was disputed from the first by embryologists. Reichert, in 1840, declared that he was unable to observe the formation of cell-elements in structureless blastema, and Remak combatted the theory of free cell-development as quite as unlikely as that of *generatio æquivoca* for living creatures. Doubtless the credit of bringing forward the axiom '*omnis cellula e cellula*' is due to Virchow; for, although Goodsir (*Anatomical and Pathological Observations*, Edin., 1845) and Redfern had described the multiplication of cartilage-cells, their observations remained unheeded till Virchow described the same process to occur in the other connective tissues, the corpuscles of which he made the progenitors of all pathological processes, and the germinative basis of all new growths. Although he did not deny that epithelial cells could reproduce their like, and thus form excrescences such as warts, he considered that the cells of connective tissue could also, by a kind of diseased action, produce epithelium, and this mode of development he believed to be the distinctive characteristic of cancrroid and carcinoma. He described the process as commencing by the nucleation and cellation of connective tissue corpuscles giving rise to an enormous number of small round cells, which, while in an undifferentiated state, he called formative cells (*Bildungszellen*). These then become gradually converted into elements of an epithelial type. This view, which Virchow upheld in both his great works (*Loc. cit.* and *Cellular Pathologie*) with such wonderful power, had certainly the merit of putting out of the field the exudation theory of the humoral pathologists, and bringing the cell forward as the important element.

About the same time, Remak discovered that the earliest trace of the embryo was divisible into three layers, the upper and lower of which were destined to form the skin and mucous tract, and received the names horny and glandular respectively, while the middle layer was devoted to the development of the

intermediate tissues, namely, the connective tissue and its derivatives. He laid down that these three germinal layers not only remained distinct throughout the development of the animal, but that in the adult the descendants of each layer were quite independent, and could only reproduce their like in regenerative processes; thus from epithelia came epithelium, and from connective tissue some form of connective tissue. He also applied this view to the formation of tumours, and said it was more easy to imagine that a small portion of the epithelial germ-layer which had been cut off from the rest or gone astray in the early stages of the development of the fœtus, could, after remaining latent many years become active, and produce a growth with elements similar to its progenitor, than that cells could arise by a form of spontaneous generation in blastema, or in a pathological exudation.

It is, however, to Thiersch's work on epithelioma, published in 1865 (*Der Epitheliakrebs, namentlich der Haut*), that we are indebted for bringing Remak's law of development to bear on the growth of tumours. He endorsed Remak's views, and disputed the power which had been attributed by Virchow to the connective tissue of producing epithelium. After an exhaustive historical and critical review of the literature of epithelioma or cancrroid, he positively states, that the epithelial masses, to which this form of cancer owes its name, does not come from the connective tissues, and he founds his opinion on prolonged personal experience, of which he gives ample evidence by detailing an immense number of accurately observed and beautifully illustrated cases. He supports his views on the following grounds. 1. The transformation from a connective tissue corpuscle to an epithelial cell has never been directly observed. 2. Such a transition is directly opposed to the rules which have been observed to take place in the development of the embryo. 3. It is not supported by the mode by which epithelium is regenerated. 4. Such a theory is unnecessary, as this form of tumour may always be traced to some pre-existing epithelium. 5. The cell-multiplication in the connective tissue of the stroma, is easily explained by the secondary irritation caused by epithelial growth. He considers the starting-point of the process to be a loss of histogenetic equilibrium between the epithelium and the subjacent connective tissue, which latter has lost power with age, while the epithelium has retained its histogenetic energy. An undue proliferation of the under layers of epithelium thus occurs, by which processes are sent down into the connective tissue, which in its turn changes more or less its character, just as it does in the development of many glands, teeth, etc., which start from a dipping in of the external skin. Thus he not only deprived the connective tissue of its power of producing epithelium, but he also gave the epithelium the credit of taking the first step in the process of the development of epithelial tumours.

This was a serious divergence from Virchow's views, and seemed to get a helping hand from the investigations of His, who removed one of the great difficulties with which Remak and Thiersch had to deal (*Die Häute und Höhlen des Körpers*, Basel, 1865). He showed that the cells lining the connective tissue cavities—serous sacs, vessels, etc.—were not really epithelium in the same sense as that on the cutaneous and mucous surfaces, but that they were rather a modification of the connective tissue cells;

and he proposed for them the name 'endothelium,' to distinguish these cells from true epithelium, as he believed they had no connection either with the horny or mucous layer of the embryo.

The cell-elements which are crowded together in the alveoli of carcinoma have been usually acknowledged to resemble epithelial cells, since Virchow called attention to the likeness in his first paper on the subject in 1845 (*Archiv*, Band i.). The modern French school has laid more particular stress on this likeness, and suggested the term 'Epithelial new growth,' instead of carcinoma. The great majority of pathologists who have observed this similarity subscribe to Virchow's doctrine, that the connective tissue is the germinative basis of all pathological change, while Remak's and Thiersch's ideas received but little attention.

However, in an able article published in 1868, (*Archiv*, Band xli.) Waldeyer not only endorsed Thiersch's theory, but extended it to carcinoma; the exclusive origin of which he traced to epitheliiform cells. For him there is no difference between carcinoma and epithelioma, except that their situations lead to different destinies. In all true carcinomata, as in cancrroid, he recognises epithelial cells as the essential characteristic, and thinks the changes which the various tumours ultimately undergo, depend upon the natural degenerative tendency of the epithelium from which it springs. Thus in skin-cancers we frequently find the formation of hard masses of cells, like the horny layer of the cuticle, while in the breast fatty degeneration commonly occurs, which change he regards as an abortive attempt at the formation of milk. After a clear description of the disease in all its favourite seats, he comes to the conclusion, 'that carcinoma is essentially an epithelial growth, and that it only occurs primarily where true epithelium already exists. Secondary carcinomata can only be produced by the direct propagation of the epithelial cells, which may be transported from their primary seat either through the lymph-vessels, or, as embola, are carried through the blood-vessels to a suitable place, where they develop like the germs of entozoa.' He calls attention to the fact that all the common seats of carcinoma are intimately connected with epithelium. He does not believe that the tumours frequently described as true specimens of carcinoma occurring primarily in connective tissue, really belong to that class; and he states that all those diagnosticated as such, which he has had an opportunity of examining, have turned out to be varieties of sarcoma. He describes the mode in which the cells penetrate the tissues, and crowd in the lymph-spaces, so as to form a kind of network. They may also extend to the lymph-vessels, which can be seen distended on the surface of some of the serous membranes. In the solid parts, the tissue between the lymph-spaces forms the reticula of the cancerous stroma, which becomes gradually denser and thicker from the chronic irritation kept up in it by the cell-masses in the spaces producing proliferation of the connective tissue corpuscles. To this source he attributes the broods of small cells which are constantly found in the fibrous trabeculae, and which Virchow thought to be the earlier stages of the epitheliiform cells he saw in such numbers in the alveoli. With regard to the first step in the process, Waldeyer does not agree with Thiersch, as he says, in old age the regenerative power of epithelium is rather diminished, in comparison with

that of the connective tissues, and he believes the disease starts in the connective tissue; which becomes hypertrophied, indurated, and irregularly contracted, probably cutting off from the rest small portions of epithelium, which then rapidly multiply.

In 1869 the views of Thiersch and Waldeyer met an opponent in Köster (*Entwicklung der Carcinome und Sarkome*, Würzburg). This author, following a point suggested by von Recklinghausen, attributes the origin of the 'cancer-cylinders,' as he calls the cell-masses which occur in cancrroid, to the proliferation of the cells lining the lymph-vessels. He disbelieves in Remak's views on development, and discards the name given by His to the cells lining the connective tissue cavities, and, neglecting the distinction, persists in calling them epithelium. He makes fine sections parallel to the surface, as in examining the subcutaneous lymph-vessels, and he describes appearances which may be thus briefly enumerated.

1. In the peripheral parts of all epitheliomata, anastomoses may be seen to take place between the cancer-cylinders.
2. These anastomoses form networks, which in every respect correspond to the plexus of lymphatic vessels under the skin, and appear to be formed of prolongations from them.
3. Often in the centre of these cylinders of cells a round space or lumen exists, which is filled with a material of different refracting power.
4. Sometimes the cylinders are pierced by blood-vessels.
5. The cancer-cylinders are not bounded by any *membrana propria*. From these observations, he thinks he can safely conclude that the cancer-cylinders represent altered lymphatic vessels. By the use of silver impregnation, he is also able to persuade himself that the epithelium of the young cancer-channels behaves in the same way to silver salts, as that of lymph-vessels, with which it agrees exactly in its relations and distribution, but the vessels are no longer covered with the normal epithelium of lymphatics; on the contrary, the cells are opaque, thick and rounded, and he could find every stage of gradation from the normal epithelium to the well marked cancer-cell. He then concludes, that not only do the cancer-cylinders correspond to lymph-vessels, but the epitheliiform cells, which are crowded together in them, are the direct offspring of the pre-existing epithelial cells lining those vessels. He denies that the connective tissue takes any active part in the growth; and even the small cell-brood in the tissue between the cancer-cylinders, he regards as white blood-corpuscles which have wandered out of the vessels. The cells, he thinks, under ordinary circumstances, would pass into the lymph-vessels, and thence back to the blood, but in cancer they cannot do so on account of the lymph-spaces being plugged with epithelial cells; thus he thinks the partial obliteration of the lymph-channels would quite account for the masses of small cells in the connective tissue.

Köster believes that the skin plays but a passive rôle, and has nothing to do with the starting of the disease. Great development of the cuticle, and hypertrophy of the hair-bulbs and papillae, do certainly occur, but only as a secondary affection, depending upon the cancerous degeneration of the epithelium of the lymph-vessels, which excites the neighbouring parts to increased action. This is then quite a new source for the cell-elements in cancer, by which Köster rejects not only Remak's view of development, and denies the purity of descent which Thiersch and

Waldeyer ascribe to pathological epithelial growths, but also takes from the connective tissue the germinative power given it by Virchow.

In 1870 Dr. Classen, of Rostock, made an attack upon the views of Thiersch and Waldeyer, from a different standpoint (*Virchow's Archiv*, Band iv.) The groundwork upon which his theory is built is the emigration of the white blood-corpuscles from the vessels, a process which was first observed by Waller, and subsequently was used by Cohnheim in 1867, as the weapon with which he made his surprisingly successful attack on the schema of cell-division as described by Virchow, after it had reigned supreme for many years in all the schools of Europe. Having demonstrated the wandering capabilities of the white blood-cells during inflammation, he declared their emigration from the vessels to be the great essential in the process, and said that white cells were the only source of pus, boldly demanding, 'Who has ever seen the division of a cell taking place?'

Dr. Classen attempts to depose cell-division from its last holding, by handing over the monopoly of all heterogeneous growths to the white blood-cells, by which accession they hold the same position exactly, as was formerly given by Virchow to the connective corpuscles, which are, according to Dr. Classen, to be regarded as superannuated and useless elements. The white cells of the blood have a great deal to answer for since their erratic propensities were discovered.

Dr. Classen's views are based upon a single case of epithelioma of the sclerotic and cornea, in parts of which he found many newly formed blood-vessels packed with white blood-cells, while here and there such numbers had escaped that the tissue around the vessels was thickly studded with them. These cells, Classen thinks, were transformed into the characteristic elements of epithelioma; they also formed the connective tissue stroma, and the thickening of the conjunctival epithelium. In fact, the ultimate destiny of the white blood-cell only depended upon the peculiar characters of the locality to which it emigrates. The tissue becomes cleft and penetrated in all directions by the increasing number of cell-emigrants, which are rapidly changed to the epithelial type by their associates. During these changes, the cornea-corpuscles can be observed to remain unaltered. He believes the blood-vessels to be the starting-point of the growth; the following being the steps in its progress. In some place, which is covered with epithelium, and which has been for a long time in a state of hyperæmia, arise an immense number of small round cells, which have probably left the vessels, or are at least seen to follow their course in the earlier stages. These cells crowd into the connective tissue spaces, and at the same time assume an epithelial form. The cuticle over the part increases in thickness by the addition of many small round cells, which have the same origin as those in the connective tissue. The growth then encroaches on the neighbouring tissues, being preceded by a continuous formation of new vessels, etc.

In 1872 a second paper from Waldeyer on the development of cancer appeared, in which he adhered firmly to his former opinions (*Virchow's Archiv*, Band lv. p. 67.) He admits the frequent emigration of the blood-cells, but protests against the histogenetic omnipotence given them by some authors. He quite recognises the value of Biesiadecki's discovery, namely, that wandering cells are commonly

found in epithelium; but he disputes their convertibility into epithelial cells, which theory he considers to be an unwarrantable assumption, contradicted by a great number of direct observations of the regeneration of epithelium from old epithelial cells. He has long recognised the fact that the lymph-vessels were the natural channels by which the cancer processes should extend; but he denies that Köster has brought forward any satisfactory proof of the development of the cells from endothelium; and he deems it strange that he, and all other investigators who have repeated his experiments, have failed in producing the preparations he described.

In 1872 Dr. Carmalt (*Virchow's Archiv*, Bd. lv.) attempted to follow Köster's observations, but found that the cells could be displaced from the lymph-vessels in which they were packed by shaking the thin sections, and that when stained with silver they constantly showed the marking of normal endothelium. By examining perfectly fresh specimens with care on a warm stage, he was able to see and demonstrate the fact, that many of the cells lying in the spaces were capable of active amœboid movements. From this he concludes that, though the epithelial cells commonly lie in the lymph-vessels, their presence then is due to their own movements, and not to the propagation of the cells lining the vessels.

In 1873 Dr. Woodward (Toner Lectures), who is well known for his microscopic photographs, published a lecture in which he appears to confirm Classen's observations, and attributes to the white blood-cells the power of producing all the cell elements of cancer.

Last year Perewerseff (*Journal de l'Anatomie et de Physiologie*, 1874) investigated the model of propagation of four cases of carcinoma of the stomach. He could trace the disease in each case to the pre-existing epithelium which penetrated the perivascular lymph-spaces. In the deeper parts also, the spread of the disease followed the course of physiological resorption. He never could find the endothelium of the lymph-channels taking part in the production of the carcinoma-cells; but they rather underwent fatty degeneration.

From the foregoing, it will appear that our knowledge of the structure of tumours has made great progress within the past decennium. The question of the development of carcinoma is far from decided, and a wide field is left open to the workers in the young science of histology. The weight of evidence, however, appears to be in favour of the view, and all the so-called heterogeneous cells of carcinoma are always descended from pre-existing epithelial cells. The acceptance of this theory may force us to restrict our ideas of carcinoma to a small compass, and, with Billroth (*Chirurg. Pathologie*) and Waldeyer to exclude many of the growths commonly placed in that group. But it certainly is more definite than any of the ideas given by other authors, and we generally find that the limits of each group of diseases grow narrower the more definite and accurate our knowledge respecting it becomes.

PUGH ON THE HISTORY AND PROPERTIES OF GUARANA.

The subjoined article by Dr. Finley Pugh, in the *Richmond and Louisville Medical Journal*, gives the most complete account of this remedy which we have met.

Guarana is sometimes called '*Uarrana*,' also '*Narana*,' the latter name signifying a climbing plant, and the former, it is said, having been taken from a tribe of aborigines called '*Guaranis*.' It is sometimes called *Paullinia*, from the generic title of the plant from which it is obtained. It is also known as Brazilian cocoa. This substance is prepared by the South American Indians from the seeds of *Paullinia Sorbilis*, a climber belonging to the class and order octandria trigynia of the Linnæan system, and the natural family of the Sapindaceæ or soapwort order, growing in Brazil; it is also abundant in the province of the Amazonas, along the banks of the Tapajos, Rio Negro, etc., as well as in Guiana and Venezuela.

Paullinia Sorbilis, in a wild state, grows to a height of from thirty-six to forty feet, but its seeds only are used by the natives. Those of the cultivated plant are reserved exclusively for the preparation of guarana for the market. The plant is best propagated from the cuttings, but may also be grown from the seed. It produces fruit from the third year after planting, and thenceforward requires to be pruned precisely as a vine. It flowers in July, and the fruit is ripe in November. The fruit is said to be nearly as large as a walnut, and contains five or six seeds. This is one of the rare specimens of the family, for it will be remembered that the fruits of plants of this order commonly have but two or three seeds. By careful cultivation each stem will furnish four kilos, or about nine pounds of seed annually, and will live for forty years. The fruit of the plant cultivated in the neighbourhood of Mauke is preferred. The Manchees prepare it as follows. They remove the seeds from the capsules in November and dry them in the rays of the sun. After having slightly roasted them over a charcoal fire, they reduce them to a fine powder in stone mortars or in stones hollowed for the purpose; they then moisten the powder with a little water and expose it to the dew by night. In this way they produce a hard paste, often increased in bulk by mixing seeds and fragments of seeds. They afterwards roll it into cylinders of twelve to sixteen ounces each, rounded at each extremity. These cylinders or rolls are dried in the sun or in the chimneys of their huts. They are sometimes called '*guarana bread*,' and are so hard that they have to be broken with an axe, or reduced to powder by means of a rasp. The different manipulations by which the mass is rendered hard conduce to its preservation in a perfect state for many years.

For exportation, the cylinders are enveloped in cocoa-nut leaves and packed in baskets; and in this form guarana appears in the European markets, though it is said that the samples sent from the province of the Amazons to the Paris Exhibition resembled pine-apples in form.

Guarana, perfectly pure when fractured, has a marbled appearance, or rather the appearance of a piece of mosaic work, generally of a darkish or reddish brown colour. The surface is of a shiny or greasy appearance, and the structure amygdaloid. In the middle of somewhat uniform masses are imbedded smaller morsels of two or three millimètres in diameter (one-twelfth to one-eighth of an inch), of which some are of a darker and others of a lighter shade than the mass itself. Almost all of these are covered over with a whitish layer, not clearly definable. The substance is very hard, and is crushed with difficulty in a mortar. The powder is of a bright brown or cinnamon colour, but with very

little smell. But when it has been closely corked up for some time, or when it has been left a few instants in contact with the sides of a hot vessel, it acquires a peculiar odour. Heated slightly in the open air, it has the smell and taste of roasted coffee.

True guarana is distinguished from the inferior qualities by its greater hardness and specific gravity; the powder being of a reddish gray, whilst that of the sophisticated product is of a whiter appearance. Guarana is for the Indians at the same time an indispensable aliment and an universal remedy. They live almost entirely on what is called '*agua branca*,' a mixture of the powder and cold water, somewhat resembling chocolate. They reduce the mass to powder by means of a particular kind of fish-bone, or by sharp stones. The Indians have all the appearance of the freshness and vigour of those who live on animal food. They make use of it, medicinally prepared, with great success in the cases of diarrhoea and dysentery so frequent and so serious in their country; and in convalescent stages it is used as a tonic and stomachic.

The Brazilians and civilised Indians learned from the Manchees the value of guarana, and at first bought it at very high prices. They employ it for the same purpose, modifying its bitter and styptic taste by means of sugar. It is now found in several pharmacopœias. I have noticed it in the German *Pharmacopœia*. It is classed amongst the non-official preparations in the *United States Dispensatory*. It is considered specially efficacious in sick-headache. Something over a year ago it was introduced into this country. It has been my privilege to see its effects in several cases of sick-headache, and in each case it acted very efficiently and promptly; but I have searched the journals (American) in vain for cases treated by it; in fact, it has not come into very general use as yet.

M. Fournier gives as the result of his analysis of guarana, besides tannate of caffeine, the following principles: gum, starch, an acrid, green fixed oil, a concrete volatile oil, scarcely soluble in water, a peculiar principle not precisely determined, and tannic acid. Although caffeine, theine, and guaranine are identical in composition, it seems more proper and convenient to apply to each its separate name, for in this way we are enabled to know the source of our alkaloid from its name, and if we apply the name theine to the alkaloid from tea, and caffeine to that from coffee, why not guaranine to that from guarana?

Caffeine or guaranine is a compound which presents a high degree of interest, both from the metamorphoses of which it is susceptible and from the circumstance that it affords an ingredient in four substances, viz., the coffee and tea plants, the Paraguay tea, and the *Paullinia Sorbilis*, one or the other of which constitutes a portion of the daily diet of three-fourths of the human race.

The fact of its discovery in these different plants belonging to distinct natural families, is a highly interesting result of recent chemical investigations. That these different shrubs should have been selected by different nations for the purpose of yielding a beverage, when infused with boiling water (and in the case of *Paullinia* with cold water) shows that the ingredient which they furnish is one which is adapted in a special manner to some craving of the human frame. The use of coffee as an article of diet appears to exercise an important influence in retarding the waste of the tissues of the body, since

it was observed that during its use the proportion of phosphoric acid and of urea excreted by the kidneys was much smaller than when the coffee was omitted. When a solution of pure caffeine was substituted for the ordinary infusion of coffee, similar alterations were produced in the quality of the urine; hence it is concluded that caffeine, likewise, exerted a power of retarding the disintegration of the constituents of the animal frame.

Tea, as used among us, is known to exhilarate without sensibly intoxicating. It excites the brain to increased activity and produces wakefulness; thence its usefulness to hard students, to those who have vigils to keep, and to persons who labour much with the head. It soothes, on the contrary, and stills the vascular system, and hence its use in inflammatory diseases and as a cure for headache. Its exciting effect upon the nerves makes it useful in counteracting the effect of opium and of fermented liquors, and the stupor sometimes produced by fever. And we would suggest guarana as a good substitute; for in these cases the effect seems to be chiefly due to the alkaloid, and it is much more abundant in guarana, as we have already seen. It contains nearly three-tenths of its weight of nitrogen; a proportion which exists in only a very small number of other known substances.

It is remarkable as being present not only in Chinese tea, but also in Maté, or Paraguay tea, in coffee, and in guarana; and again we say, it is a very curious fact, that in countries so remote from each other plants so very unlike as all these are should have been, by a kind of instinct, as it were, selected for the same purpose of yielding a slightly exciting, exhilarating, and refreshing beverage; and that these plants, when now examined by chemists, should all be found to contain the same remarkable compound body, which we call theine, caffeine, or guaranine.

The observed effects of this substance when introduced into the system, justify this conclusion, and form the third point, which is worthy of remark in regard to it. It is known that the animal body, while living, undergoes constant decay and renovation. The labours of life waste it; the food introduced into the stomach renews it. That which is wasted, off is through the lungs, the kidneys, the alimentary canal, the skin, or in other ways, rejected from the body of the animal. The solid matters contained in the urine are in some degree a measure of this waste; and especially the quantity of urea and phosphoric acid it contains, at different periods, is supposed to measure the comparative waste of the tissues at these different times.

Now the introduction into the stomach of even a minute proportion of this alkaloid—three or four grains a day—has the remarkable effect of sensibly diminishing the absolute quantity of these substances voided in a day by a healthy man living on the same kind of food and engaged in the same occupation under the same circumstances. This fact indicates that the waste of the body is lessened by the introduction of this alkaloid into the stomach—*i.e.*, by the use of coffee, tea, or guarana. And if the waste be lessened, the necessity for food to repair it will be lessened in an equal proportion. In other words, by the consumption of a certain quantity of coffee, tea, or guarana, the health and strength of the body will be maintained in an equal degree upon a smaller supply of ordinary food. These substances, therefore, save food; stand to a certain extent in the

place of aliment, while at the same time they soothe the body and enliven the mind by their tonic, happy-fying, yet harmless action upon the nervous system. Hence they are the poor man's friend, while they are the rich man's solace. In the old and infirm their use serves also another purpose; for in a majority of cases, there comes a time in their lives when the stomach no longer digests enough of the ordinary elements of food to make up for the natural daily waste of the bodily substance. At this period the substances we have mentioned come in as a medicine to arrest the waste, to keep the body from falling away so rapidly, and thus to enable the less energetic powers of digestion still to supply as much as is needed to repair the wear and tear of the solid tissues.

Dr. Gavrelle, who was formerly physician to Don Pedro, in Brazil, and there became acquainted with the virtues of this medicine, called the attention of the profession to it some years since in France. He has found it advantageous in the diarrhoea of phthisis, sick-headache, paralysis, tedious convalescence, and generally as a tonic.

The most convenient form of administration is the fluid extract; this may be given in doses of fss . to fj .

HUBERT ON ANTENATAL BAPTISM.

In the *Cours d'Accouchements*, a recent work on obstetrics by Dr. L. J. Hubert, Obstetric Professor in the Catholic University of Louvain, especially dedicated to the young gentlemen who come to that University to receive their medical education, the author finishes by a special chapter on the subject of antenatal baptism of infants.

When an infant is not in immediate danger of death, it is at the church and by a priest it should be baptised; but when its life is imperilled, baptism may be conferred everywhere and by everybody (ecclesiastic or laic, man or woman, believer or infidel), and it is valid, provided it is administered with the intention, the material, and with the formula required.

Who, in case of peril, should administer baptism?

If the child be born, and a priest be present, he should always perform the rite. The father or mother may perform it only in the absence of any other qualified person. If the infant be born, and there be a man present capable of performing it, he should do it in preference to any woman, or even a midwife. But if the foetus be not born, baptism *in utero* should be administered, either by the obstetrician or midwife in attendance.

The general purpose or intention to do what the Church does is sufficient.

The material is water, pure water, from spring, river or well, and whether previously blessed or not.

The formula is: I baptise you in the name of the Father, of the Son, and of the Holy Spirit.

This formula should be distinctly articulated, and loud enough to be audible to the person himself.

The baptism is absolute or conditional according to circumstances, as we shall proceed to show. The manner varies as to whether the child is born or not.

A. If the child be born, the baptiser should himself pour water on the head of the child at three times, corresponding with the mention of the respective names of the Holy Trinity.

If there be any doubt respecting the life of the new-born, the formula should be modified thus: 'If thou art living, I baptise thee, etc.'

If there exist any doubt of the human nature of the being to be baptised (viz., if a marked monstrosity or rudimentary embryo), it should be added, 'If you are a rational being, I baptise you,' etc. Abortions should receive the rite in the same manner and modified in the same manner as the infant at term.

If the ovum should be expelled entire, the baptism should first be done through the membranes saying: 'If you are fit to receive baptism I baptise you,' etc., then having opened the membranes the rite is repeated, adding, 'if thou hast not been baptised.' When the baptism is thus conditional, the conditions mentioned must be distinctly articulated; it is not sufficient merely to think or to will it. Such is the canonical law.

B. Supposing the foetus is still in whole, or in part unborn, it then becomes necessary to baptise it *in utero*, varying the method according to circumstances.

a. If the head be delivered, it may be baptised either absolutely or conditionally, as if the birth were completed, and no subsequent baptism will be required.

b. But if an arm or a foot present, these parts should be baptised, and the danger persisting, the chest and the head should be baptised, with the formula: 'If thou hast not been baptised,' etc.

c. But if the foetus be still enclosed in the uterus, the baptism should be performed by carrying the fingers, or a piece of lint, or sponge, or using a syphon or syringe, and with the formula as before stated, and modified according to the circumstances. After birth, it may be rebaptised, if alive.

ANATOMY AND PHYSIOLOGY.

VON BASCH ON THE ARREST OF INTESTINAL MOVEMENTS BY IRRITATION OF THE SPLANCHNICS.—Dr. Von Basch (Stricker's *Medicinische Jahrbuch.*, 1874, p. 45) has made a series of experiments in order to determine whether the splanchnic nerves arrest the motion of the intestines by acting directly on their motor ganglia in the same way as the vagus stops the heart, or whether they do so by causing contraction of the intestinal blood-vessels, and thus removing from the intestinal ganglia the blood which acted as a stimulus to them and produced the movements.

The author finds that a convenient way of exciting peristaltic action is to inject nicotine into the veins of an animal. The injection causes immediate tetanus of the intestine, followed first by absolute rest, and then by active peristaltic movements. These movements, as well as those which occur after opening the abdominal cavity without administration of nicotine, can be completely arrested by irritation of the splanchnics, and the intestine also becomes dilated and flaccid. The cessation of movement and relaxation of the muscular fibres, however, do not always occur at the same moment, for sometimes the circular fibres of the gut remain in a state of tonic contraction when all movement has stopped and the longitudinal fibres are completely at rest. The action of the splanchnic nerves in arresting the movements of the intestines was considered by Pflüger to be of the same nature as the action of the vagus in arresting the movements of the heart; but the author was led to the conclusion

that Pflüger's notion was incorrect, by former experiments made by him in conjunction with S. Meyer. At the time when Pflüger wrote, it was generally believed that complete anæmia of the intestine was a cause of movement; but their experiments showed that a diminution in the quantity of blood contained in the intestinal vessels did not occasion intestinal movements, and that the cause of increased peristalsis was to be sought for in the condition of the blood, not in its quantity. They therefore considered that the splanchnics arrested intestinal movements by causing contraction of the intestinal vessels, and thus expelling from the walls of the intestines the blood which would stimulate them to movement. Their explanation has received additional confirmation from the experiments mentioned by the author in this paper, which show that, when the peristaltic movements occur after the injection of nicotine, the blood-pressure continues to sink, indicating that the intestinal vessels have become dilated. The increased movement is attributed to the dilated vessels allowing more blood to circulate in the intestine, and thus increasing the stimulus to their action. When the splanchnics are irritated the intestinal vessels contract, the blood-pressure rises, and the peristaltic movements cease. The arrest of peristalsis occurs at the same time that the blood-pressure reaches its maximum. Both of them occur during irritation of the nerve if it be long continued, but if the irritation be short they both occur after it has ceased. Meyer and the author found that the intestinal movements can be sometimes arrested by stopping the circulation either by ligaturing the thoracic aorta or by irritating the vagus until the heart ceases to beat. Neither of these methods answer well when the peristalsis has been excited by nicotine, as the vessels are dilated by the drug and contain much blood even after ligature of the aorta, and the vagus is also much weakened and does not stop the heart. Irritation of the medulla oblongata in curarised animals has exactly the same effect as irritation of the splanchnics. The blood-pressure will rise and the intestines come to rest on irritation of the medulla, even after both splanchnics have been divided, but not so constantly as when these nerves are intact. The results of irritation of the medulla after division of the splanchnics were not alike in all individuals. In some the intestines stopped, in others irritation of the medulla had little effect. In those where the intestines stopped the blood-pressure rose high, while in the others it only rose slightly. The reason of this variation in the results of irritation in different animals, is that the vaso-motor nerves of the intestine are not all contained in the splanchnics greater and less, but are given off in the roots of all the sympathetic ganglia. When the splanchnics are divided, their place is supplied to a greater or less extent by the other vaso-motor nerves which pass from the lumbar portion of the spinal cord to the abdominal vessels. In the dog this occurs to a considerable extent; but it is slight in the rabbit, which has most of the vaso-motor fibres for the intestinal vessels in the splanchnics. Irritation of the medulla has little action on the intestinal vessels or peristaltic action if the splanchnics have been divided in any animal where the vaso-motor fibres are chiefly contained in these nerves; but it will continue to have an effect if the vaso-motor fibres pass to the intestines by other channels. When the vaso-motor nerves are too weak for irritation of the medulla to cause com-

plete contraction of the vessels, and thus stop the intestinal movements so long as the heart is propelling the blood onwards, these effects may be produced by ligaturing the aorta before the irritation is applied to the medulla. The compression must not be applied at too short intervals or continued too long, or the irritation will cease to have any effect; but if care be taken in these respects, the experiment may be repeated ten or twenty times. When the aorta is ligatured, irritation of the medulla causes very little change in the blood-pressure; it quickens the pulse which had been slowed by nicotine. Stoppage of the respiration irritates the vaso-motor centrum by rendering the blood going to it venous, and produces the same effects as irritation of the medulla, both when the splanchnics are cut and when they are whole. If small quantities of nicotine be injected while the intestines are moving, they immediately make a sudden movement and then stand still. At the commencement of the stand-still the circular fibres are tonically contracted, so that the intestines seem in a state of tetanus. This lasts for some time, and then they gradually and completely relax. This occurs, whether the spinal cord or splanchnics are whole or divided.

SURGERY.

DOWELL ON RADICAL CURE FOR HERNIA.—Dr. Greenville Dowell, of Galveston, thus describes (*Transactions Texas Medical Society*, 1874) his plan for the radical cure of hernia. The only instruments used are a double spear-pointed semi-circular needle, with an eye in each point, silver wire, a piece of cork, soft wood, or roll of adhesive plaster. The parts being well shaven, three lines are drawn with a brush and tincture of iodine, parallel to the direction of the hernial orifice, the centre line being immediately over the internal orifice and passing down to the external orifice, if the hernia be oblique inguinal; in other varieties, immediately over the greatest enlargement of the tumour. The needle is then taken hold of by the left hand at its unthreaded end; then the right hand, with the thumb and forefinger, pulls up the skin and superficial fascia as high as it can be done to the right of the middle line, letting the middle line be just below the point of the thumb. The threaded end is then pushed through the fold held below the point of the thumb and index finger. The fold is then let loose, and the threaded end taken by its point with the thumb and fingers of the right hand; it is then pulled on until the unthreaded end comes just under the outside line of right side of the operator, and left side of patient. The index finger of the left hand is made to invaginate the integuments as far as possible, and the finger is pushed

to the right under the left tendon of patient, feeling well the wall. The right hand then raises the needle, so as to have its point directly over the point of the finger and a little to the outside of it. The needle is then pushed directly down through the tendon into the peritoneal cavity; at this stage, the point of the index finger of the left hand is carried to the right side of the patient, and held under the tendons; the needle is then moved about to see if it be loose, and turned in its curve so as to carry the curved portion of its point under the invaginated integuments, etc., to about one-quarter of an inch of the right tendon; the end is then brought out on the outside line of the patient's right side; this is done by pressing down on the threaded end held by the surgeon's right hand. The index finger of the left hand is then taken out, and the threaded end let go, and the unthreaded end is taken hold of by the right thumb and index finger of the right hand. It is now gently pulled on until the threaded end comes above the tendon. The point threaded is then reversed, and keeping well down on the tendon, is finally pushed out at the first puncture and pulled entirely out, leaving the two ends of the ligature close together in the same puncture. We have thus put a ligature entirely around the two sides of the rupture, with a sufficient portion of the tendon and muscles to give the thread sufficient surface to act on; and now, by pulling on the two ends, the rupture is closed internally by the replacing of its natural support, and then the ends are tied around a piece of cork or soft wood. If one ligature do not close the opening so that the point of the finger cannot be pushed under the wire, another wire is put in in the same way. Before tying the first, enough must be put in to completely close the rupture, and they should not be more than a quarter or half an inch apart.

The operation can be performed on either side; but it is best in inguinal hernia to start the needle from the side opposite to the ilio-pubic ligament. This enables the needle to be pushed down by the side of the ligament.

This method is simple and easy to perform, and is applicable to all external herniæ. The process is the same, and made with the same needle and silver wire. Of course, it is not applicable to internal hernia, as diaphragmatic, obturatic, ischiatic, entrocystic, invaginal, vaginal and rectal, as they cannot be reached without resorting to the direct method, which ought to be done in all cases of strangulated hernia, when this needle will much facilitate a closure of the incision.

The wires are to be left in from four to seven days, according to the inflammation of the parts. Lotion of sugar of lead and morphine are to be applied externally, according to circumstances.

HAMILTON ON THE DIAGNOSIS OF DISLOCATIONS OF THE SHOULDER.—The *New York Medical Record* of March 27, contains an abstract of a clinical lecture on dislocation of the shoulder by Dr. F. H. Hamilton, author of the well-known work on *Fractures and Dislocations*. After remarking on the frequency of errors in the diagnosis of these cases he gives the following simple method of deciding whether or not the humerus has been displaced. If the result of this examination points to the existence of a dislocation the direction must be ascertained by the aid of the signs usually given by surgical writers.

First. While the head of the humerus remains in

its socket, if a rule be laid upon the outside of the arm from the shoulder to the elbow, it will not touch the acromion process, but will be distant from it at least half an inch, generally one inch or more. On the other hand, if the bone be removed from the socket, in whatever direction it may be displaced, whether forwards, downwards, or backwards, unless the shoulder is much swollen, the rule, placed in the manner above stated will touch the acromion process.

Second. If, standing behind the patient (in case of the right shoulder), the thumb and forefinger of the left hand be made to grasp the top of the shoulder in such a manner that the interdigital commissure shall rest upon the acromion process just outside of the acromio-clavicular articulation; and if then the finger and thumb be dropped perpendicularly, the tip of the finger will (in case the head of the humerus is not dislocated) rest upon the centre of the round upper extremity of the humerus, as it projects in front of the acromion process, while the end of the thumb will rest upon the head of the humerus behind; but the head will be felt indistinctly by the thumb, for the reason that, instead of projecting as it does in front, it actually recedes a little beneath the acromion process. Up to this moment, the surgeon may entertain some doubt whether he is actually grasping with his thumb and finger the head of the bone; but if he now move the elbow of the injured limb forwards, so as to carry the head of the humerus backwards in its socket, he will feel it press strongly upon the thumb, and this will be conclusive. If a dislocation exist, the head of the bone cannot be felt in this situation, and by the thumb thus placed.

J. W. LANGMORE, M.D.

BERTHOLDT ON DISLOCATION OF A CERVICAL VERTEBRA.—Dr. Bertholdt, of Nürnberg, communicates (*Aerztliches Intelligenz-Blatt*, April 6, 1875) the following case of dislocation of the sixth cervical vertebra towards the right side. The patient was a young man, aged nineteen, who, in washing his neck, sharply turned his head towards the left side, and felt a crack on the right, accompanied by severe pain, and inability to get his head back again into its proper position. An hour afterwards he was seen by Dr. Bertholdt, who found him with the face congested and red, the head askew, the chin resting on the left shoulder. On the right side there was stretching and undue prominence of the muscles of the neck, and on the left a corresponding hollow. The spinous processes of the cervical vertebrae were not in a straight line but in a curve, the convexity of which was directed towards the right side. The patient complained of intense pain in the neck, and any attempt at movement was unbearable. The diagnosis was easy. Reduction was attempted in the following way. Dr. Bertholdt got on a stool and fixed the patient's head by taking the occiput and chin in both hands, making extension upwards, using the weight of the body for counter-extension, and by means of a subsequent rotary movement, the dislocation was reduced. The patient was able to move his head readily in all directions afterwards, and soon recovered.

LANGENBECK ON RESECTION OF THE WRIST-JOINT.—At a meeting of the Berlin Medical Society, January 10, 1875 (*Berliner Klinische Wochenschrift*), Professor von Langenbeck brought forward two cases in which he had operated for resection of the wrist-joint.

Resections of the wrist-joint at the commencement of disease are rare, the operation being generally undertaken later on. It is frequently performed on account of tuberculous inflammation, which appears in the form of synovitis. Before suppurative sets in, the bones of the wrist become movable, as the fungous granulations of the synovial membrane destroy the ligaments, thus separating the articulations.

The first case shown was that of a man aged twenty-two, of scrofulous appearance since his sixth year. Some years before, Bürow, of Königsberg, had extirpated the third metacarpal bone, and four years afterwards fresh caries appeared in the metacarpus. Resection by means of the dorso-radial incision was performed, removing all the carpal bones, two metacarpal, and the articular surface of the forearm. Tolerably rapid healing followed in the permanent water bath; fistulous tracks, however, remained, probably occasioned by newly formed bone, subsequently necrosing. The tendons were singularly atrophied. A very satisfactory result followed after active and passive motion, the patient being able to seize objects with the fingers, and to lift any light weight.

The second case was that of a woman, aged forty-four, of a phthisical family. Inflammation commenced in the wrist-joint in October, 1874, and a few weeks later the carpal bones became loosened. Seven weeks after the outset of the disease, excision was performed by means of the dorso-radial incision, and all the carpal bones, except the cuneiform and pisiform, were removed, as well as the articular surface of the bones of the forearm. The synovial membrane was much degenerated, and the intercarpal ligaments were destroyed, so that the removal of the bones was remarkably easy. The patient speedily recovered.

MATERIA MEDICA AND THERAPEUTICS.

GRESLON ON THE USE OF CHLORAL IN THE TREATMENT OF WHOOPING COUGH.—Dr. Greslon reports, in *La France Médicale* for April 3, a case in which the patient, a child eight years old, having always enjoyed good health, had a violent attack of whooping-cough. Dr. Greslon observed the case for six weeks. The cough, which at the commencement was almost incessant, went on to very frequent paroxysms of the most marked character, accompanied by vomiting, and especially

by intense fits of suffocation, which constituted the leading characteristic of the attack.

All the remedies usually employed in such cases, opiates, antispasmodics, etc., having had no results, Dr. Greslon tried chloral in doses of fifteen to thirty grains every night. After the administration of this drug, the patient, who was then in the most violent stage of whooping-cough, having on an average a fit every hour throughout the twenty-four, showed a sensible improvement of the symptoms. In four days' time only five or six attacks occurred during the day, and the nights were calm. The symptoms from that time gradually diminished, until, in about ten days after this treatment had commenced, the patient had only two or three attacks in the twenty-four hours, and they were also greatly diminished in length and intensity. The patient, who was very much lowered, recovered his cheerfulness and his usual state of health. Fifteen days elapsed between the first administration of chloral and the cessation of the fits of coughing, so that the action of the drug was very rapid.

CRÉQUY ON JABORANDI IN PLEURITIC EFFUSION.—M. Créquy communicated to the Paris Société de Thérapeutique at their meeting on March 10 (*Bulletin Général de Thérapeutique*, March 30) the case of a man, aged fifty-five, who was attacked on January 10 with pleurisy of the left side. Notwithstanding treatment consisting of purgatives, diuretics, blisters, etc., the effusion increased daily, and the heart was displaced to the right side. Jaborandi was first administered on February 12, in a dose of five grammes (75 grains), which was repeated on February 13, 16, 18, 19, 22, 24, and 28, and March 1; under its influence the effusion was gradually re-absorbed, and each day a notable diminution was observed. The patient is now completely cured.

M. Dujardin de Savignac has sometimes employed jaborandi, and has remarked the facility with which this drug, even in small doses, induces vomiting. To remedy this inconvenience, M. Dujardin Beaumetz uses jaborandi as enemata in doses of 100 grammes of water. These enemata produce salivation and perspiration. In a recent case of uræmia, he used subcutaneous injections of jaborandi with advantage, concentrating into one gramme of liquid the infusion of three grammes of jaborandi leaves. These injections did not bring on any local irritation.

GONTIER ON THE TREATMENT OF TRAUMATIC TETANUS BY HYDRATE OF CHLORAL.—Dr. Gontier, in his *Thèse de Paris*, December, 1874, reports twelve cases of tetanus treated by chloral. An analysis of these leads to the following conclusions. Chloral may render great service in the treatment of chronic or subacute tetanus, and is especially preferable to other drugs. It is completely inefficacious in acute tetanus, and only has a slight palliative action. It may be advantageously associated with tonics diffusible stimulants, and diaphoretics. Intravenous injections of chloral are extremely dangerous, and should in the present state of science be reserved for exceptional cases only.

UNOFFICIAL FORMULÆ.—The following are selected from the unofficial formulæ reported by J. F. Hancock at the last meeting of the American Pharmaceutical Association.

Balsamic Diachylon Ointment (Hebra's Ointment): \mathcal{R} . Pure olive oil, $\mathfrak{f}\mathfrak{z}\mathfrak{x}\mathfrak{v}\mathfrak{j}$; oxide of lead, $\mathfrak{z}\mathfrak{i}\mathfrak{i}\mathfrak{j} + \mathfrak{z}\mathfrak{i}\mathfrak{j}$;

distilled water, $\mathfrak{O}\mathfrak{i}\mathfrak{j}$; oil of lavender, $\mathfrak{f}\mathfrak{z}\mathfrak{i}\mathfrak{j}$; Peruvian balsam, $\mathfrak{f}\mathfrak{z}\mathfrak{j}$. To the olive oil add half a pint of water and mix thoroughly; then sprinkle in the oxide of lead and again stir well. Place the vessel containing the mixture in a water-bath and stir briskly until the combination is complete. When the ointment is cold add the oil of lavender and the Peruvian balsam, and mix intimately; lastly add the remaining water.

Benzoated Oxide of Zinc Ointment (Kemp's formula): \mathcal{R} . Lard and olive oil, each, $\mathfrak{z}\mathfrak{v}$; white wax and spermaceti, each, $\mathfrak{z}\mathfrak{i}\mathfrak{j}\mathfrak{s}\mathfrak{s}$; oxide of zinc, $\mathfrak{z}\mathfrak{i}\mathfrak{j}\mathfrak{s}\mathfrak{s}$; pulverised gum benzoin, $\mathfrak{z}\mathfrak{s}\mathfrak{s}$. Mix and make according to art.

Tincture of Gelsemium: \mathcal{R} . Gelsemium, in fine powder, $\mathfrak{z}\mathfrak{i}\mathfrak{v}$; diluted alcohol, $\mathfrak{f}\mathfrak{z}\mathfrak{x}\mathfrak{i}\mathfrak{j}$. Macerate fifteen days and filter, or prepare by percolation, making the product measure twelve fluid ounces.

Chloroform and Aconite Liniment: \mathcal{R} . Chloroform, $\mathfrak{f}\mathfrak{z}\mathfrak{i}\mathfrak{j}$; tincture of aconite root, $\mathfrak{f}\mathfrak{z}\mathfrak{i}\mathfrak{j}$; soap liniment, $\mathfrak{f}\mathfrak{z}\mathfrak{x}\mathfrak{i}\mathfrak{j}$. Mix them. This preparation has been in use many years in Baltimore under the names of 'compound chloroform liniment,' and 'chloroform and aconite liniment.'

Stokes's Liniment: \mathcal{R} . Oil of turpentine, $\mathfrak{f}\mathfrak{z}\mathfrak{i}\mathfrak{i}\mathfrak{j}$; strong acetic acid, $\mathfrak{f}\mathfrak{z}\mathfrak{s}\mathfrak{s}$; yolk of egg, \mathfrak{i} ; rose-water, $\mathfrak{f}\mathfrak{z}\mathfrak{i}\mathfrak{i}\mathfrak{j}$; oil of lemon, $\mathfrak{f}\mathfrak{z}\mathfrak{j}$. Mix.

Aromatic Syrup of Senna: \mathcal{R} . Alexandria senna, $\mathfrak{z}\mathfrak{i}\mathfrak{v}$; jalap, $\mathfrak{z}\mathfrak{i}\mathfrak{s}\mathfrak{s}$; rhubarb, $\mathfrak{z}\mathfrak{s}\mathfrak{s}$; cinnamon and clove, each, $\mathfrak{z}\mathfrak{j}$; nutmeg, $\mathfrak{z}\mathfrak{s}\mathfrak{s}$; oil of lemon, $\mathfrak{M}\mathfrak{x}\mathfrak{x}$; sugar, $\mathfrak{z}\mathfrak{x}\mathfrak{x}\mathfrak{i}\mathfrak{v}$; dilute alcohol, $\mathfrak{q}\mathfrak{s}$. Reduce the root, leaves, and spices to a moderately fine powder, and treat with the diluted alcohol, by percolation, to exhaustion; when about one quart has passed, evaporate by means of a water-bath to eighteen fluid ounces, and filter if necessary. Then add the sugar and dissolve by water-bath heat; when cold, add the oil of lemon. The product should measure thirty-two fluid ounces.

Compound Tincture of Opium (diarrhœa mixture; formula of Dr. E. R. Squibb): \mathcal{R} . Tincture of opium, $\mathfrak{f}\mathfrak{z}\mathfrak{j}$; tincture of capsicum, $\mathfrak{f}\mathfrak{z}\mathfrak{j}$; spirits of camphor, $\mathfrak{f}\mathfrak{z}\mathfrak{j}$; purified chloroform, $\mathfrak{f}\mathfrak{z}\mathfrak{i}\mathfrak{i}\mathfrak{j}$; stronger alcohol, $\mathfrak{q}\mathfrak{s}$, ad $\mathfrak{f}\mathfrak{z}\mathfrak{v}$. Mix. Dose, one teaspoonful in water for adults.

OBSTETRICS AND GYNÆCOLOGY.

GUEDES ON A CASE OF RECTO-VAGINAL FISTULA; PARTURITION PER ANUM.—At the meeting of the Lisbon Medical Society on February 13 (*O Correio Medico de Lisboa*, February 22), Dr. Ramiro Guedes related an interesting case which had occurred to him.

On April 20, 1874, being then in practice in the country, he was called to see a woman, about thirty-five years old, who was in labour for the third time. Her first labour was difficult, though not requiring instrumental treatment; the child was still-born. In her second labour, the medical man who attended her found it necessary to remove the child, which was dead. The operation was followed by a recto-vaginal fistula, with its attendant inconveniences.

Labour had commenced during the night. When Dr. Guedes was called to her late in the day, he found that she had a dry tongue, thirst, loss of appetite, and repeated bilious vomiting. The slightest pressure produced severe pain in the abdomen, which was much distended, not only by

the fœtus, but by meteorism. The pulse was imperceptible, the breathing anxious and frequent; and the colour of the skin was higher than normal. There was some vesical and rectal tenesmus, and absolute impossibility to void urine or fœces. The uterine contractions were very energetic and frequent.

On examination, the labia were found extremely swollen, red, and tender, as was also the whole perineal region. The vagina was inaccessible to digital exploration for more than about 1·6 inches, in consequence of the general swelling of its tissues, and of the presence of two resisting planes, one above (the patient lying on her back) formed by the pubic arch, and the other below by the head of the fœtus. The head of the fœtus presented at the anus, which was somewhat dilated; the occiput apparently corresponded to the anterior part of the rectum. No force was capable of moving the head from its position.

As the patient was suffering from intense peritonitis, Dr. Guedes judged that it would be useless to attempt to relieve her by perineotomy or any other operation. She died the day after his visit; a necropsy could not be obtained.

In the discussion which followed, Dr. Alves Branco advocated perineotomy in such cases, if the child were alive. Dr. Guedes replied that he had not performed this operation, because the woman was moribund with intense peritonitis, and the fœtus was dead.

A. HENRY, M.D.

WILLIAMS ON THE PERIODICAL RENEWAL OF THE MUCOUS MEMBRANE OF THE UTERUS.—The numbers of the *Obstetrical Journal* for February and March contain an account by Dr. John Williams, Assistant Obstetric Physician to University College Hospital, of some very carefully conducted investigations into the minute anatomy of the mucous membrane of the uterus, with special reference to the changes which are coincident with the phenomena of menstruation.

Until quite lately, menstruation was generally thought to be due to a periodic congestion of the uterus—a form of erection—and that during the interval the organ was in a passive state. More recent observers have shown that the period of uterine activity occupies a longer time than had been previously supposed; they believe that the organ is in an active state of preparation for some time before the actual flow appears, and that another interval elapses after its cessation before the organ returns to a state of rest. Dr. Williams shows, however, that there is no period of rest, that the menstrual flow is only the terminal phenomenon of a cycle of changes which require for their completion the whole intermenstrual period. He gives a detailed account of these changes, as shown by a careful examination of the uteri of twelve women who had died at different known stages of the menstrual or intermenstrual period. Starting from a time just antecedent to the appearance of the menstrual flow, the cycle of changes shown by these twelve specimens is briefly as follows.

1. Acute fatty degeneration of the uterine mucous membrane; this is well marked before any extravasation of blood appears. It begins just inside the internal os, and extends upwards.

2. Beneath this degenerating membrane the subjacent muscular wall is congested, and covered with a layer of actively proliferating cells—the first step towards the formation of a new lining membrane.

3. The hæmorrhage next appears; Dr. Williams believes that this is partly due to the fatty change in the mucous membrane and the active congestion of the subjacent tissue, and partly to muscular contraction of the uterus itself. He finds that the cavity of the organ when menstruation is over, though larger than usual, is smaller than it would be after removal of its lining membrane had not contraction taken place. He found also that, in specimens examined during the flow, the muscular wall was firm and pale, while the peritoneum and broad ligaments were congested. He thinks, therefore, that the contraction of the uterus drives the blood from the muscular wall into the mucous and serous membranes; the contents of the glands and the greater part of their lining epithelium are expelled at the same time.

4. When hæmorrhage has taken place into the degenerated membrane, it undergoes rapid and complete disintegration; in some cases it is entirely removed in three or four days, in others the process occupies seven or eight days.

5. During all this time cell-formation proceeds actively in the subjacent layer; three days after the cessation of the catamenia the lower two-thirds, and at the end of a week the whole, of the body of the uterus is lined with a thin mucous membrane, covered by a fresh growth of columnar epithelium. It is, however, at first of a very rudimentary character, and it is not till just before the period of the next flux that the membrane becomes structurally perfect. If impregnation now occur, it undergoes further development, but failing this, the same series of changes again commences. Menstruation is, therefore, due neither to congestion nor to a species of erection, but to a molecular disintegration of the mucous membrane of the body of the uterus, accompanied by hæmorrhage. The paper is illustrated by some beautifully executed drawings, showing the microscopical appearance of the uterine mucous membrane at different stages of this physiological process.

MATTHEWS DUNCAN ON PUERPERAL ECLAMPSIA. The April number of the *Practitioner* contains notes of an interesting clinical lecture on puerperal eclampsia, by Dr. Matthews Duncan, from which we take the following remarks on the etiology and treatment of that disease.

Dr. Duncan thinks that undue importance has been attached to Bright's disease as a cause of convulsions in pregnant women. That Bright's disease, if present, greatly predisposes the patient to convulsions there is no doubt, but in a large number of cases the fits cannot fairly be ascribed to this cause. It is exceedingly common to find a small quantity of albumen in the urine of pregnant women near the full time, and still more common to find it after fits have occurred, just as it may be found after an epileptic attack. Slight glycosuria may also be found under the same conditions, but the woman would not, therefore, be said to be suffering from diabetes mellitus, neither can she be said to be suffering from Bright's disease because there is a temporary appearance of albumen in the urine.

The fact is that pregnancy itself induces temporarily in a healthy woman a condition of things very like that which is produced in a more chronic form by Bright's disease. Thus healthy women are known to become hydremic in advanced pregnancy; the researches of Gessner show that a woman gains considerably in weight, excluding the weight of the

gravid uterus. Recent investigations by Spiegelberg and Gscheidlen indicate that there is a plethora of this watery blood. Some unpublished researches of Dr. Hardie indicate an increase in the quantity of urea in the blood. The presence of an increased amount of urea in the blood causes, as Mahomed has recently described, contraction of the small arteries and increased blood-pressure; to overcome this, increased power in the action of the heart is needed. To a woman in this condition come the throes of labour, which interfere with the regularity of respiration and suddenly increase the cerebral blood-pressure, flushing the face. It does not seem wonderful that, under this combination of circumstances, fits should occur, and that they should often appear to recur simultaneously with the pains.

As to treatment, Dr. Duncan can lay down no general rule; each case must be treated on its own merits. The most important object is to empty the uterus; but even in this great discretion is necessary, and, if labour be only commencing, forcible delivery should only be performed if the symptoms are becoming desperate, *i.e.*, if the fits become more frequent and severe, and especially if the patient becomes paler and more cyanotic, her breathing shallower, and the coma more profound. It is well to get a free evacuation of the bowels, and the urine should be drawn off and examined. Bleeding, he thinks, is only useful to tide over a crisis; it often produces great temporary relief, but if the cause of the malady be still present, the improvement may be but of short duration. Chloroform and chloral are sometimes useful, but occasionally appear to do harm; and if respiration be imperfect and much cyanosis be present, chloroform must be used with great caution.

BRUNTON ON THE TREATMENT OF PROLAPSED FUNIS.—Dr. J. Brunton calls attention, in the April number of the *Obstetrical Journal*, to a mode of treating this troublesome complication of labour which, though proposed and fully described in 1858 by Dr. Thomas, of New York, has only quite recently found a place in the ordinary text-books of midwifery, and is not as generally known throughout the profession as its success and simplicity deserve. The older obstetricians recommend under these circumstances that delivery should be expeditiously effected by turning or by the use of the forceps, or, if these means cannot be used, that the cord should be pushed up into the uterus, either on the finger or by the aid of a flexible catheter or a piece of whalebone; these expedients are, however, often troublesome to perform, and are in most instances only temporarily successful.

Dr. Thomas was the first to recognise the importance of placing the patient in a favourable attitude before making these attempts at reduction. He found that by placing the woman on her knees with her head down on the bed, 'in the posture assumed by eastern nations in worship,' the cord could not only be readily replaced, but that, if the patient be kept in this attitude until a pain has occurred, a return of the prolapse is much less likely to happen. By placing the woman in this 'knee-elbow position' the cord tends to fall back into the uterus by its own weight; and since the contraction of the uterus at each pain commences at the neck and gradually passes upwards, the cord, once within the cervix, is helped on by the advancing contraction, and fixed in some new position. If it be not thought desirable to place the patient in this crouching posture, she should

be laid on the side opposite to that on which the funis has prolapsed, and the pelvis should be raised by placing pillows under it. Dr. Brunton has adopted Dr. Thomas's plan for some years past with the greatest success; he relates several cases in illustration of its value.

THOMAS ON THE TREATMENT OF EXTRA-UTERINE FETATION BY OPERATION.—On February 7 last, Dr. Thomas, of New York, operated successfully on a case of extra-uterine foetation. He first made an opening into the sac through the vaginal wall, using the galvano-cautery in order to avoid hæmorrhage. Then, seizing the feet, he brought the body of the foetus through the aperture, using a small pair of forceps to extract the head. Part of the placenta came away readily; but in the attempt to get the remaining portion, such profuse hæmorrhage came on that he was obliged to inject a solution of persulphate of iron into the sac, afterwards packing it with cotton-wool. With the exception of some slight symptoms of septicæmia, which soon disappeared under the persistent use of an injection of carbolic water, the patient's recovery was without a drawback. This was the seventh case of extra-uterine pregnancy which Dr. Thomas had seen; all the others had proved fatal except one, in which the foetus was passed by the rectum. In making the diagnosis of extra-uterine pregnancy, Dr. Thomas lays great stress upon the spasmodic attacks of agonising pain, which show that the dilated Fallopian tube has begun to contract upon its contents. This is Nature's warning; and, unless prompt interference be attempted, rupture of the cyst and fatal collapse are almost certain to follow. The case is reported in full in the *American Medical Weekly*.

NOURSE ON A REMARKABLE SUCCESSION OF BREECH-PRESENTATIONS.—Dr. Nourse relates in the *Cincinnati Clinic* the case of a lady, aged forty-three, who had been married twenty-five years, and had given birth to eleven children, all, without an exception, being breech-presentations. The mother was a healthy woman, of medium height, and had a well-developed pelvis. The children were also well-developed, of fair size, and with heads quite as large as usual. There was nothing remarkable about the labours, except the regular occurrence of the exceptional presentation. Numerous theories have, he says, been brought forward to account for the great frequency of head-presentations, and deviations from this rule have been thought to be due to various accidental causes; but none of the prevailing theories will satisfactorily explain eleven successive breech-presentations in the same person.

MEDICAL JURISPRUDENCE.

SANTLUSS ON THE CONDITIONS OF INSANITY IN MEN, AND THEIR BEARING ON RESPONSIBILITY.*

Under the terms insanity, madness, mania, passion, etc., authors have included very various significations. For the most part, reference has been intended to excessive disturbances of the will, to so-called hyperboulia, to *perversæ voluntates*; and different classifications have been proposed, according as their objects and exciting causes corresponded with the disturbed passion or mania. Hence we have had for instance religious mania, political fanaticism, and a whole crowd of monomanias, whose ontological distinctions Marc has made to coincide, it is well known, with their external objects, according as one or another special eccentric, emotional, or voluntary passion appeared the central point of the diseased and excited condition or affection. We have only to recollect the instinctive and furious manias, as erotomania, suicidal mania, demonomania, kleptomania, and finally pyromania, whose special forms have long been recognised by German authors, and have been treated of by them at the greatest length, but which have not even yet been reduced to any simpler classification. Upon the classification attempted from the iracundia morbosa of Platner to the kleptomania and arson introduced by Casper as ghosts into forensic medicine, depends a whole chain of opinions and views, which have on the whole tended rather to obscure than to make clear the nature of insane conditions. Hence it happens that even at the present time the existence of the specific forms and kinds of mania (as, for example, mania for arson) has on the one hand been denied altogether, and on the other the most contradictory opinions have been promulgated concerning them in different handbooks of forensic medicine.

Considering the very various views held upon raptus maniacus, furor transitorius, insania occulta, etc., the confusion as to their nature and existence is not to be wondered at, nor is it surprising that in recent times many attempts have been made to fix their forensic meaning. From this point of view a threefold inquiry has been raised, whether, namely, (1) attacks of furor transitorius are the consequence of a previously existing mental disease; (2) or whether they occur in previously healthy persons; or whether (3) their very existence is to be called in question. But though authors differed thus widely in their views of these diseases, the relations of the maladies to justice and responsibility were felt to be of greater interest and importance than disputes of writers concerning their nature. And in consequence of this the medical faculty of Bordeaux offered a prize in 1861 on this question: Can disorders of will arise without disorder of intellect; and under what circumstances is irresponsibility for such conditions to be assumed in the sufferers, and what effect should they have on punishment? In Germany also Krävel took a similar line, and insisted on the position that between sanity and insanity there was a borderland of doubtful ground, as there is between day and night a condi-

tion of twilight. In this intermediate state consciousness was not, he contended, quite lost, but was perturbed, and allowance must be made for it in adjudging punishment.

In the following essay the question will be raised, 'Does a periodic madness exist?' Now all nature seems to afford point to the analogical reasoning that there is such a condition. The chyme and blood-phenomena of animals, the phenomena of the vegetable kingdom, and the periodic alteration in the activity of animals, their development, hybernation, and so on, all point in this direction. A similar view is strengthened by the study of the phenomena of polarity, by the maximum and minimum of the pulse, of the ebb and flow of disease-processes and of the phenomena of neuroses and neuralgiæ, etc. From all these, it appears that the basis of paroxysms of violence must be a permanent deflection of the mind, a view supported by the ancients, e.g. Trallianus and Aretæus. Other authorities, as Thomasius, Justinian, etc., deny the existence of the lucid interval. So much for periodic mania in which there are no clear intervals between the attacks.

Quite otherwise is it as regards furor transitorius, mania transitoria. In this the attacks break out like clouds from a clear sky, not preceded by any mental disturbance, and often followed by perfect recovery. Mania *a potu*, mania *e partu*, satyriasis, etc., belong to this group. The difference between the periodic mania and the transitory mania is precisely that between remittent and intermittent fever.

An examination of the views of Platner shows that he recognises two forms of mental disease, which he calls real and unreal. In the real, a desire to attain some real good or ward off some real evil is accompanied by an attack of violence; while in the unreal, the onset of violence deceives partly itself and partly others. Now, sometimes the irritating causes are so violent and continuous that a man may approach insanity. Anyone approaching it so far as to stand between fury and madness will be in a condition above fury (though scarcely mad), and in this class of diseases the insanity cannot be so much said to have intervals of health as that health is interrupted by attacks of deflection of the mind. This go-between state it is of great consequence, on account of public security, to recognise, as it is quite as necessary to punish this hybrid condition of insanity as it is to protect people from it. Platner therefore recognises two kinds of fury:

1. Habitual or real—the consequence of perpetual excitement in the sense or faculty of craving for things (*Begehrungsvermögen*);

2. Acute or unreal—the consequence of morbid irritability of the nerves. Acute fury and furor transitorius are therefore identical.

If fury is but a condition of passion (not accompanied by unconscious causes leading to unreasonable actions) it will not belong to the sphere of mental diseases. For example, it would be wrong to say that, because a man suffered from a choleric and melancholic temperament, passion for drink or sexuality, therefore he was mad, such being in truth moral capacities and energy, contributing to his moral culture and being the basis of his *ego*. Now the question arises—When do these passions change into a morbid mental condition? When is fury, be it furor transitorius or iracundia morbosa, to be looked on as a disease of the mind? The answer would be: Passions are morbid when combined

* From the literary remains of Dr. Santluss, of Diez, published by his son, Ed. Santluss.

with a perversion of the consciousness of motives; consciousness is alienated when the clear representation of object and purpose are not realised by the *ego*. On examining persons affected in these ways, we generally find disturbances in the circulation of the blood, etc. Such intensification of the sentiments may lead to loss of reason.

It may be assumed that in status iracundiosus there is a constitutio iracundiosa which stands in the same relation to exandescencia furibunda as habitus apoplecticus does to apoplectic paralysis. It is wrong to say that psychic diseases (consequently also fury) depend on necessity (*Unfreiheit*). Psychic diseases are the cause of necessity (*Unfreiheit*); and where the attacks of fury are not preceded by a mental alienation there is no morbid fury. As Seneca says: 'For insanity (like anger) is equally unable to effect its purpose, unmindful of what is fitting, forgetful of necessity, pertinacious and dogged in what it has undertaken, shut off from reason and counsel, agitated by trifles, incapable of looking at the true and the right, and very like those ruins which weigh down that on which they fall.' And in another place: 'You may know that they who are possessed by anger are not sane, but are too introspective.'

The existence, therefore, of an independent morbid fury is evident; and in those suffering from it there is not a proper agreement between subject and object.

As for insania occulta, the phenomena of vaccination and of germination prove the possibility and also the probability of a latent disease. In the law courts, the existence of insania occulta is admitted only when it shows itself in psychic perversion. In the sphere of pathology, the latent existence has been long accepted.

Raptus means any passing ecstasy, moral or religious; any violent and sudden exaltation in consequence of any sudden confusion of the will. Hence we speak of raptus ebriosus, libidinosus, erotomaniosus, etc. The nun Blankenbinn, who took a lamb (the lamb Jesus) into bed with her and embraced it, was in a state of erotic ecstasy, but was not in a state of raptus furiosus. Had she killed the lamb in her embraces, the condition would have been one of raptus furiosus, because it led to a violent action. Drunkenness is not a raptus unless followed by a violent or unconscious action; while, if it be thus followed by some illegal action, the raptus is identical with furor transitorius. There is no other distinction than this to be made between these two—that furor transitorius can develop a chronic character, while raptus has reference only to quite sudden foolish behaviour.

It will consistently satisfy the author's point of view to reduce all the conditions of madness mentioned (even iracundia morbose and insania occulta) to furor transitorius, periodicus, and chronicus, and to call it simply furor. The following theoretical classification of furor is given:

1. *Furor libidinosus*: *Sense-madness*.—Arising from wrong activity of the will. Consciousness shows itself in a morbid, violent manner.

2. *Furor hyperscepticus*: *Intellect-madness*.—To this belong mania for collecting, disputing, etc.

3. *Furor ecstaticus*: *Emotion-madness*.—To this belong furor religiosus, platonius, epidemicus seu imitatorius, etc.

The distinction between mania and furor is shown by a story by Reil. A woman during her pregnancy has an incessant craving to eat the flesh of her

husband. She kills him, and pickles him. The killing was the furor, the craving was the mania.

Insane conditions with regard to responsibility.—Mania must not be grounded only upon the morbid sphere of the will, but upon the entire faculties of the mind. The will, before it becomes action, must be impregnated with the consciousness of those conditions which will follow the action. Will, therefore, is nothing defining, but something defined by imagination and accompanying sensations. Therefore mania arises solely from morbid elements of the will, and not from the other faculties of the mind.

Man may become mad in all directions of his mental faculties.—The non-observance of this fact has produced much confusion in the science (?) of mania, because authors were unable to imagine furor without distractions. If will cannot be conceived as apart from consciousness, and therefore apart from the remaining mental faculties, then the thesis will be correct, that with deranged consciousness all psychic actions may change into exaltation, be it as furor transitorius or periodicus. Idiots, whose consciousness is almost *nil*, show this. They are subject to periodic and habitual sexual mania. Thus also people who are deaf and dumb. In educated people we observe maniacal fits in the form of mind-disturbance (*Intellektio-wucht*) and emotional disturbance (*Ideal-wucht*).

The following principle is granted psychologically. Fury may arise not only from a perverted sphere of the will, but from any other perversion of the mind; consequently, also from consciousness; but this principle frequently breaks down from a forensic point of view, as fits of madness (in Germany) are measured by their results in practical law; hence arose the idea of 'free' and 'necessary' (*unfrei*).

[The author then, in the pages following, (1) proceeds to comment on the bearing of free and necessary (*unfrei*) on the German penal code, and (2) indulges in a philological disquisition on the word 'free,' which cannot be condensed, particularly as Dr. Santluss, jun., seems himself to have become hopelessly confused as regards the former, without which the latter is unintelligible.]

The condition of the will, and consciousness of motives, is a matter belonging to forensic psychology—to the medical man; the law (*sollen*) is a matter belonging to the judge.

Man is irresponsible when the following items have not been realised by his consciousness:

- | | |
|---------------------------------|-----------------------------|
| 1. Representative of the object | } Consciousness of motives. |
| 2. " consequence | |
| 3. " purpose | |
| 4. " of his own ego. | |

A judge should be satisfied with the predication mad or not mad, for the purpose of finding evidence for the responsibility of the accused.

The question then arises, how to define responsibility. All human mental activities are based upon consciousness, will; and the fact that our intellect, our reason, is in conformity with reality and truth or fact, justifies us in assuming that we have the right knowledge of our doings and desires; in fact, that we are reasonable, and are able to will the good and true. Quotations are here made from Cicero and Sophocles to point the author's conclusions.

A. RABAGLIATI, M.D. (Bradford).

DERMATOLOGY.

HEIBERG ON LEPTUS AUTUMNALIS.—Dr. Heiberg (*Nordiskt Medicinskt Arkiv*, vol. vi. no. 25), remarks that this troublesome parasite (our well-known harvest-bug) gives rise in a certain village of Denmark towards the end of summer to an epidemic which the inhabitants call by a name translated 'boutons d'Août.' All the parasites found by Heiberg belonged to the small red form distinguished by Gudden, and believed to be the male larva. It is clear that the insect cannot go through its transformations normally on the human subject, and the author conjectures that birds are the usual hosts of the parasite. He recommends tincture of the flowers of *Pyrethrum caucasicum*, applied as a lotion, both as a prophylactic and to relieve the symptoms.

NEW INVENTION.

FARABEUF'S NEW FORCEPS FOR REDUCING DISLOCATIONS OF THE PHALANGES.

Many methods and various instruments have been proposed to reduce the most common of these dislocations, those of the thumb; but, up to the present time, none of the plans proposed have been of much avail.

was an old man who had had dislocation of the thumb for twenty-four days. The new forceps was successful in breaking the very solid adhesions in every direction and in replacing the thumb without chloroform, in a short space of time, and without at all excoriating the skin. The patient left the hospital after having worn a retaining apparatus for a fortnight. M. Guyon's patient was a young man who had been suffering from a complete luxation backward of the right thumb for forty-eight hours. Chloroformisation was complete, and after failure of methodised and powerful manipulations reduction was obtained with the new forceps, M. Guyon being able to bend, draw, and twist the thumb as he pleased, while an assistant, fixing the metacarpal bone, used his thumbs in coaptation. Considerable force and some time were needed to replace the phalanx, and the forceps never gave any sign of

The forceps *à courroie* does not take a firm grip, can only draw, and generally slip if it is somewhat forcibly drawn. It is quite wanting in regard to movements of flexion and extension, and torsion, which should be used to the luxated part during traction. It also embarrasses the field of the dislocation, and prevents the assistant from firmly fixing the member and also the coaptation.

The new phalanx forceps constructed by M. Farabeuf for M. Collin is not open to the same objections. It is a very simple instrument, which seizes the finger as a *porte-abat-jour* forceps seizes the bougie on which it is fixed. The concavity of the blades and their dimensions have been so calculated as to perfectly embrace the body of the phalanges; the blades of the instrument are finished off by enclosing them in a strong India-rubber tube.

When applied, for instance, to the first phalanx of the thumb, this forceps cannot leave hold even when it is handled by a feeble hand. The movements of extension, flexion, and torsion, the shakings, the sharp tractions, are performed with great strength. On the dead body even the strongest ligaments are broken with facility and without any trace of contusion on the skin. There is, therefore, no reason for continuing to make groping and hazardous subcutaneous sections in difficult luxations. The power of the instrument in its present condition has appeared quite sufficient, and it has purposely been constructed in a light and simple form without any complications likely to unduly develop its power or modify its mode of action. MM. Trélat, Labbé, and Guyon have afforded M. Farabeuf three opportunities of observing dislocations of the thumb. M. Trélat's patient had a dislocation of the thumb backward, which could not be reduced by the forceps *à courroie*, but which yielded to simple coaptation. M. Labbé's patient

slipping, nor was it necessary to repeat the operation. These three dislocations were gradually reduced without the least shock, noise, or concussion.

MISCELLANY.

NORTH LONDON MEDICAL SOCIETY.—A meeting of medical practitioners was held on Wednesday evening, April 14, at the Athenæum, Camden Road, to confirm the proceedings of previous meetings held for the purpose of establishing the above society. The ordinary meetings of this society will be held at the Athenæum, on the second Wednesday in each month, from October to May. It is proposed at these meetings to discuss short papers and records of cases. The following gentlemen were elected officers of the society:—*President*, W. B. Kesteven, Esq.; *Vice-President*, T. S. Dowse, M.D.; *Treasurer*, R. H. Hilliard, M.D.; *Secretary*, W. H. Kesteven, Esq.

THE LATE DR. RUSH.—In a biographical sketch of the late Dr. Rush, of Philadelphia, it is stated that it was he who said, 'Let my epitaph be, He fed fevers.'

FOUR AT A BIRTH.—*The Baltimorean* of February 20 reports the case of Mrs. John R. Hahn, of Baltimore, who gave birth, on February 16, 1875, to four female infants, all of them 'fine, fat, healthy, handsome children.' Mrs. H. is a small, delicate woman, about thirty years of age, born of Irish parents in Baltimore. Physicians from Philadelphia, Harrisburg, Washington, Alexandria, etc., are said to have visited Baltimore to see this remarkable mother and her remarkable progeny.

A USEFUL EXPERIMENT.—In view of the recent unmeasured denunciation of the practice of experiments on animals, it is pleasant to be able to direct attention to an instance in which a human life was saved by the practical application of the latest researches on animals made by the Edinburgh committee on behalf of the British Medical Association. The case is recorded by Dr. Ogilvie Will in the *Edinburgh Medical Journal*, and is one of strychnia poisoning successfully treated by hydrate of chloral. The antagonistic action of hydrate of chloral to strychnia had been proved by this committee, by means of those experiments on animals which have created much indignation in the minds of persons who are doubtless unaware of the inestimable value of such investigations in the mitigation of human pain and suffering.

PROFESSOR BUFALINI of Florence, the author of a well-known essay on Life, and of an esteemed work on Analytical Pathology, died at Florence on March 30, in the eighty-eighth year of his age. His funeral ceremonies were performed on the most splendid scale, and were attended by representatives of all the learned societies of Italy and the Universities of Pisa, Rome, Palermo, Maurata, Pavia, Modena, Padua, and Turin. Amongst the pall-bearers were the Italian ministers of agriculture, commerce and public instruction; the Mayor, and the Prefect of Florence, the President of the Institute, and the President of the Medico-Chirurgical Association. By his will Professor Bufalini has left a prize of 10,000 francs to be awarded every ten years to the writer of the best essay on the true indications of the experimental method in all scientific researches and acquisitions, which shall also embody the applications attained by the divers sciences, and the progress which the experimental method has made, during the period which has elapsed between two competitions.

NURSING IN PHILADELPHIA.—The first training-school for nurses was opened in Philadelphia, in 1839, by Dr. Joseph Warrington, in connection with the lying-in hospital. Dr. Warrington's object primarily was, 'to supply respectable women with medical aid; secondly, to establish a school in which young physicians could become familiar with obstetrics, and good women be trained to become their assistants, and be fitted to take care, not only of the poor, but also of the wealthy patient.' In 1861, when the Women's Hospital was chartered, a training-school for nurses was specifically mentioned as one of its branches; and up to 1872, though in a small way, such training was carried on. In 1872 an endowment of about nine thousand dollars placed the school upon a sure foundation, and thus far forty-six nurses have been under instruction; forty-one of this number have graduated. At the Episcopal Hospital is also a nurses' training-school, which, however, is not yet properly developed. The main difficulty in the way of organising a regular body of trained nurses in Philadelphia, as in other places, is the trouble experienced in finding women who are suitable for the work. During seventeen years two hundred and seventy-five women applied for admission to the school of the lying-in hospital. Only eighty-six were admitted. At the Women's Hospital the forty-six mentioned were selected from one hundred applicants.

THE JACKSONIAN PROFESSORSHIP of Cambridge has been conferred on Mr. Dewar, all the other candidates having withdrawn. Mr. Dewar is widely known as a gifted investigator as well as a first-rate teacher, and his presence at Cambridge will be a great gain, not only to that University, but to English science.

HOW TO KEEP FLOWERS FRESH.—The *Bulletin Français* contains some curious details on the employment of camphor as a means of preventing flowers from withering and of quickening the development of seeds. This stimulant action of camphor was known as far back as 1798, when Benjamin Barton had the idea of placing a tulip in a solution of camphor. The tulip grew vigorously, and greatly outstripped its companions grown with ordinary water. A yellow iris having withered, Barton watered it with camphorated water, and it revived. M. Vogel, of Munich, who has taken up these experiments in a new form, has communicated the results to the Academy of Munich. He threw some powdered camphor into distilled water, and this water, loaded with camphor, acted as a strong tonic on the plants. Two branches of flowering syringa, of equal strength and size, were placed, the one in fresh water the other in camphorated water. A considerable difference in them was soon observed: at the end of twelve hours the branch which had been immersed in fresh water was almost dead, whilst the branch which had been placed in the camphor water was perfectly fresh and in good condition; some of the buds had become developed, and the shrub lasted for three days. In another series of experiments a branch of syringa, which was nearly dead, was placed in camphorated water, and showed marked revivification, which lasted for some time. It then occurred to M. Vogel to water the seeds with camphorated water. He chose stale seeds, which have a weaker germinative power than young ones. These seeds germinated under the influence of this treatment incomparably quicker than those which had been plunged into pure water. It may therefore be taken as proved that the development of seeds may thus be hastened and strength imparted to sickly plants.

GAS SUPERSEDED IN DAYTIME.—In these days of high prices for gas, it is well the public should be reminded of that eminently useful invention, Chappuis' Patent Daylight Reflectors. The price is moderate and the apparatus lasts for a considerable time. Prospectuses may be had at the Factory, 69 Fleet Street, London.—[ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

WEDNESDAY, APRIL 28, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

EVERS ON INDIAN MEDICINAL PLANTS.

In the *Indian Medical Gazette* of February 1 and March 1, Surgeon B. Evers, civil surgeon at Seoni, has some interesting notes on certain Indian medicinal plants. He says: My experiments with indigenous drugs were conducted chiefly with the view of finding some really useful and common antiperiodic; but other drugs attracted my attention, and so step by step I have been lured on, and now I find that a very extensive field of labour lies before all of us. For much that is contained in these papers I am indebted to the valuable works of Roxburgh, Ainslie, Lindley, Waring, Drury, and others; but at the same time I must here state that whatever confirmatory or additional information I have gained, has been obtained by personal observation and experiment. I purpose to take the various medicinal plants I have to remark on, in the order in which they have been tried by me.

Michelia champaca (Nat. Ord. Magnoliaceæ, Champa tree). I was induced to make trial of the bark of this tree as a febrifuge, from what Waring mentions. 'Further trials with this bark,' says he, 'appear desirable.' I tried a decoction of the bark in ten cases of ague, and from my own experience I can safely state that it is invaluable as a tonic and febrifuge. Dr. H. Lolliot, of Mauritius, employed it successfully 'in the treatment of the low intermittent fevers of that island.' (For directions regarding its use, see Waring's *Pharmacopœia of India*, p. 6.) The root-bark is said to be emmenagogue, but of this I have not yet had proof. 'The flowers beaten up with oil are applied to foetid discharges from the nostrils.' From information obtained through the Conservator of Forests, I learn that only one other member, viz., the *Michelia nilagirica*, of this family, is to be found in those parts. This plant is found on the Pachmari hills near the Mahadeo cavern, but in all probability it was planted there. I have not been able to make many trials with this bark, as unfortunately it is not procurable in any considerable quantity in these parts. I leave it to others to test the value of the drug.

Carica Papaya (N.O. Papayaceæ, Pawpaw tree). The milky juice of the unripe fruit has long been known as one of the best vermifuges; and in the West Indies, the seeds powdered are used for the same purpose. The seeds are said to possess emmenagogue properties also. Even the ripe fruit is said to act as an abortifacient, and pregnant women are therefore prohibited from eating it. The juice of the pulp (of the ripe fruit I imagine) removes, it is said, freckles caused by exposure to the sun. Browne, in his *Natural History of Jamaica*, states 'that water impregnated with the milky juice of this tree is thought to make all sorts of meat washed in

it tender; but eight or ten minutes steeping, it is said, will make it so soft, that it will drop in pieces from the spit, or turn soon to rags in the boiling.' Drury says that 'this circumstance has been repeatedly confirmed, and, moreover, that old hogs and old poultry, which are fed upon the leaves and fruit, however tough the meat they afford might otherwise be, are thus rendered perfectly tender and good, if eaten as soon as killed, but that the flesh passes very soon into putridity, nay, the very vapour of the tree serves the purpose; hence, many people suspend the joints of meat, fowls, etc., in the upper part of the tree, in order to prepare them for the table.' In Barbadoes, the farmers mix the milky juice with the drinking-water for their horses, for the purpose, as they express it, 'to break down the blood; and this is a remarkable fact that the effects of this dissolving power in the fruit is not confined to muscular fibre, but acts on the circulating blood.' In 1866, when I visited the island of Barbadoes, I found that the unripe fruit pickled was largely used as an article of diet. In this country it is not only eaten pickled, but also curried. I can assure my readers that the unripe fruit makes a very palatable *chijki* (vegetable curry.) I have employed the milky juice of the unripe fruit in the treatment of splenic and hepatic enlargements, and with good results. I have treated sixty patients with this drug, and in thirty-nine instances a cure was effected; in eighteen cases the results were not reported; and in three cases (of enormously enlarged spleens) relief was afforded. The mode of administration is this. About a teaspoonful of the juice is collected and mixed thoroughly with an equal quantity of sugar; this mass is divided into three boluses; one to be taken morning, noon, and evening. For children, a single drop of the juice, mixed with sugar, is sufficient. The pulp of the unripe fruit (the rind being removed) 'mashed' up with hot water, might be applied as a poultice over the enlarged gland. On this external application, however, I do not place much reliance. No ill effects result from the internal application of the drug. Some of the patients treated complained of a feeling of heat in the stomach, nothing more. When symptoms of gastric or intestinal irritation occur, I have found it necessary to combine opium or hyoscyamus with the juice. The drug appears to me to act as a tonic and deobstruent. My plan for ascertaining that there has been an actual diminution in the size of the enlarged gland, was to mark off with the nitrate of silver the limits of the affected organ when the patient applied for treatment; and after about a fortnight or month, percuss and mark off again in the same way. In very bad cases, I have seen a decrease of from half an inch to an inch in perpendicular dullness. Patients have told me again and again that they felt considerably lighter in the side; and that (*ab khana hazm hota*) their digestion was now good. I believe that the drug is most active in cases where the stage of ague-cake, i.e., the genuine amyloid spleen, has not yet been attained—in fact, when the deposit in the gland is still albuminoid. It acts much more rapidly than the hydrochlorate of ammonia, the bromide of potassium, or the external application of the biniodide of mercury ointment. From twenty to twenty-five days is the longest time that a patient is generally kept under treatment. A nutritious and liberal diet is also an essential adjunct in these cases.

Acorus calamus (N. O. Aroideæ, Sweet-flag). Ainslie says that 'it is a very favourite medicine of

the Indian practitioners, and is reckoned so valuable in the indigestion, stomach-aches, and bowel-affections of children, that there is a penalty incurred by any druggist who will not open his door in the middle of the night and sell it if demanded.' A bath made of the infusion of the root 'is regarded as an effectual remedy for epilepsy in children.' 'Shroder informs us that it possesses virtues in obstructions of the menses, spleen, and liver.' The Egyptians regard it as a valuable aromatic and stomachic. The Turks prepare a confection of the root, and employ it 'as a preventative against contagion.' 'European practitioners have considered the root as tonic and aromatic; and occasionally prescribe it in cases of intermittent fever and dyspepsia.' Dr. A. T. Thomson recommends it as an antiperiodic; and Dr. Æ. Ross reports that it is an excellent stimulant and diaphoretic; he looks upon it 'as most serviceable in atonic and choleraic diarrhœa.' As an insecticide, particularly with reference to fleas, I have always found it very efficacious; but for this purpose, the root must be obtained fresh. Last year, the chief cause of mortality among the house patients of the Seoni Main Dispensary was dysentery; the gaol population also suffered very much from the same disease. The disease is most prevalent about the middle of the rainy season, that is, during the months of July and August. The disturbance probably of the water-supply, especially when this is derived from tanks and streams, and the dampness of the season are, in some measure I think, accountable for the appearance of the disease. In many of these cases, a malarial taint could be detected. *Ipecacuanha* does not, I regret to say, always succeed in these cases. There were no less than sixty-nine cases of dysentery treated in the Main Dispensary during the months of July and August. I found a decoction of the rhizome of the *acorus calamus* very effectual in arresting the flux of blood, especially in the dysentery of children. The decoction is prepared thus: Of the bruised rhizome, two ounces; coriander seed, one drachm; black pepper, half a drachm; water, one pint; boil down to twelve ounces, and set aside to cool. The dose for an adult is an ounce three times daily; for a child, one to three drachms, sweetened with sugar, two or three times a day. Astringent extracts or quinine might be added if necessary. The decoction is not only useful in dysentery and diarrhœa, but also in the bronchitic affections of children. I have often taken it myself when suffering from a bad cold in the chest. I think the drug is one well worthy of more extended trial.

Cochlospermum gossypium (N. O. Ternströmiaceæ). The pods contain a silk-cottony substance that might be used for stuffing pillows, etc. The bark has a faint aromatic odour, and yields on scarification a resinous exudation resembling myrrh. The natives use the branches of this tree for making torches. This plant is said, like the *sterculia urens*, to yield a gum analogous to tragacanth. I have employed a decoction of the bark as a tonic and demulcent in cases of gonorrhœa. Of thirteen cases treated with the decoction, nine were decidedly cures, and in four the result was not known. The patients stated that after taking this medicine the scalding soon ceased. I found it necessary, however, to combine the sulphate or acetate of zinc in quarter-grain doses, to arrest altogether the discharge. The medicinal value of this plant is not, in my opinion, great.

Calosanthus Indica (N. O. Bignoniaceæ). The Gonds call this plant the 'jaimangal;' and it was from a Gond that I first heard of its medicinal properties. The tree is common in Bengal, Burmah, South and Central India, Ceylon and Java. According to Brandis, 'the barks and fruit are used in tanning and dyeing, the seeds are used to line hats, and placed between two layers of wicker-work to make umbrellas. Root, bark, leaves, and seeds are used in native medicine.' The Gonds employ a decoction of the bark as a discutient application to rheumatic swellings. They do not, however, administer any part of the plant as an internal remedy. I have made trial of the powder and an infusion of the bark, and have found it to be most powerfully diaphoretic; the drug has slight anodyne properties; also a bath, prepared with the bark, I have frequently employed in rheumatism. Twenty-eight cases of acute rheumatism were treated with this drug, and in all the results have been most satisfactory. The dose of the powder is from 5 to 15 grains, three daily; of the infusion (1 ounce of bark to 10 ounces of boiling water) an ounce three times a day. Combined with opium, it forms a much more powerful sudorific than the compound powder of *ipeacuanha*. The drug does not possess any febrifuge properties. Roxburgh makes no mention of the medicinal qualities of this plant.

Pongamia glabra (N. O. Leguminosæ). The natives of the south of India thread the legumes and tie them round the necks of children suffering from whooping cough. It is said by them to be of use in these cases. Probably the friction of the legumes against the chest, or it may be, the exhalation from them, might have something to do in mitigating the distressing cough. I have employed the powder of the dried pericarps in the treatment of whooping cough (fourteen cases), and in chronic bronchitis (twenty-five cases), and must acknowledge its efficacy in these affections. Most of my patients were quite relieved in from ten to twelve days. For an adult the dose of the powder ranges from five to ten grains; for children, one to three grains, thrice daily, given with a little syrup or honey. The oil obtained (by expression) from the seeds is employed by the natives in the treatment of 'scabies, herpes, and other cutaneous diseases.' It is also employed as an embrocation in rheumatic affections. According to Brandis, 'the pods and the leaves are used in native medicine.'

Holarrhena antidysenterica (N. O. Apocynaceæ. Seeds).—An infusion of 'the oat-like seeds (Anderjun of the Taleef Shereef) is said to be effectual in arresting hæmorrhage from piles.' 'In the only two cases of this affection that came under my care, I employed the drug with advantage. It is one well worthy of further trial. For further particulars regarding the value of this plant, I must refer my readers to Ainslie's *Materia Medica*, vol. i. p. 88, and to Waring's *Pharmacopœia of India*, p. 137. The bark (Conessi-bark) of this plant has long been held in high repute as a remedy for dysentery.

Jatropha curcas (N. O. Euphorbiaceæ). The juice of this plant is used by natives to arrest bleeding from wounds, etc. The seeds possess purgative properties; and the oil obtained from them is said to be useful in cutaneous affections and in chronic rheumatism. Not long since my attention was attracted to a notice of this plant in the *Indian Medical Gazette*, by Mr. Uday Chund Dutt. He reports that the milky juice of this plant is a most

powerful hæmostatic. In two cases, in which trials were made, he says that the bleeding was at once arrested; and to use his own words, '*the blood seemed to be at once curdled up.*' Before this notice appeared, I had the following case under treatment. Bugloo, aged twenty-five, was admitted into the Seoni Main Dispensary on October 3, 1874. He was suffering from a large open abscess in the heel of the right foot; the abscess had resulted from an injury. The patient stated that it was not so much the pain and swelling of the foot that caused him anxiety, but the frequent hæmorrhages from the abscess. On removing the rags, etc., that enveloped the foot, hæmorrhage (evidently venous) at once occurred. Immediately above the internal malleolus I found a pulsating tumour about the size of a pigeon's egg; pressure on the posterior tibial artery on the proximal side of the swelling at once arrested the bleeding; the superficial veins in the neighbourhood were enlarged, and a faint thrill could be detected in them. Taking into consideration the situation of the tumour, and the character of the hæmorrhage, I diagnosed the case as one of varicose aneurism. The bleeding from the tumour was easily checked by the application of the tourniquet, but the distress occasioned by the pressure of the instrument was so great, that before evening the patient begged that it might be taken off. After this, instrumental and digital pressure were resorted to alternately. In the meantime, the abscess in the heel was gradually filling up. On seeing Mr. Uday Chund Dutt's paper, I determined to give the jatropha juice a trial; and accordingly, on October 12, I injected a drachm of the juice into the tumour by means of the hypodermic syringe. The result was astonishing; in twenty minutes' time the pulsation was so faint that no non-professional person could have detected it; and by evening all pulsation had ceased, a good firm coagulum had been produced. The nozzle of the syringe was retained in the tumour for about ten minutes; and on removing the instrument just one drop of blood escaped through the puncture; a small piece of dry lint and a piece of sticking plaster were applied to the puncture. No ill effects resulted from the injection of the juice. I was anxious to watch the result of this treatment further; but on the evening of October 16 the patient left the hospital without permission, considering that it was no longer necessary for him to stay in Seoni. People from his village inform me that the man is now (fully three months after the operation) quite well. This is only a single case it is true, but it illustrates how a very simple and speedy operation may be had recourse to in place of others more serious. We all know what a difficult thing it is to treat aneurismal affections. Holmes in his *System of Surgery* (vol. iii. p. 512) has the following passage: 'The discovery of a fluid of great coagulating power, and devoid of irritating properties, is a desideratum in this method, *i.e.*, the treatment of aneurisms by injections. I make no pretensions to originality, but I ask that others with better opportunities than myself may give this drug a trial. Two children were brought to me for the purpose of having the frænum of the tongue snipped, and in both these cases, after the operation, I employed jatropha juice as a styptic; there can be no doubt of the value assigned to it by natives. The jatropha curcas is a very common hedge-plant. Drury states that the juice 'is of a very tenacious nature, and, if blown, forms large bubbles, probably owing to the presence

of caoutchouc.' 'A decoction of the leaves is used in the Cape Verd Islands to excite secretion of milk in women.'

Sesamum Indicum (N. O. Pedaliaceæ).—Not long ago I found in the *Pioneer* newspaper that the mucilage obtained from the leaves of this plant is considered a specific for dysentery in some parts of Australia, and this led me to make trial of the drug. Waring remarks on this subject: 'The leaves (*sesami folia* or *Benne leaves*) are official in the secondary list of the United States Pharmacopœia; they abound with thick viscid mucilage, which is readily imparted to water, and an infusion of them is much used in the southern states of North America in all affections requiring demulcents. One or two full-sized fresh leaves, infused or agitated in half a pint of cold water, will soon render it sufficiently viscid for the purpose. If the dried leaves be used, hot water should be substituted for the cold. How far the leaves of the Indian-grown plant may be used in this way, remains to be determined.' I have employed the mucilage, obtained from the leaves of the Indian plant, in the treatment of sixteen cases of dysentery, and in all recovery followed. From six to seven days was the time necessary for such treatment. I confess, however, that my cases were not of the virulent type seen towards the end of the rainy season. The drug acts simply as a demulcent, and does not, in my opinion, exert any specific influence on the disease; furthermore, it is necessary to combine an opiate with it, to relieve the tenesmus, so that probably the opium added has as much to do in checking the disease as the mucilage itself. Waring again states that 'the seeds have powerfully emmenagogue properties assigned to them, and it is believed by the natives and Indo-Britons that, if taken largely, they are capable of producing abortion. The alleged emmenagogue properties of these seeds deserve further investigation.' In three cases of congestive dysmenorrhœa I administered the powder of the seeds in ten-grain doses, three or four times a day, with benefit. I have at the same time employed the hip-bath recommended by Waring. It is commonly believed in the south of India that the seeds, when eaten by a pregnant woman, are likely to induce abortion; but no instance of the kind has ever come under my notice, nor have I heard of any. Further trials with the drug are necessary. The seeds of this plant yield the common til or jingelly oil of commerce. The leaves of the *Pedaliūm murere*, another plant of the same natural order, also yield a viscid mucilage when agitated in cold water. The natives use the mucilage thus obtained as a demulcent and diuretic in the treatment of gonorrhœa, and there can be no doubt of its value in such cases. The plant is very common in the south of India.

LUYS ON THE REFLEX ACTIONS OF THE BRAIN, IN THE NORMAL AND MORBID CONDITIONS OF THEIR MANIFESTATIONS.

Dr. Foville has published the following exhaustive analysis of M. Luys's very important work, in the *Annales Médico-Psychologiques*. He commences by quoting the opening passage of the book. 'The end which I have endeavoured to attain in this work is to show that, amongst the phenomena of cerebral activity, there is a whole series of manifestations, normal and pathological in an equal degree, which are of a reflex nature; that they are, in all respects,

comparable to the similar manifestations of which the medulla spinalis is the seat, and that they are performed in an automatic manner and for the most part independently of the will and the consciousness of the individual.

'In the description of the phenomena which will be submitted to review the following arrangement has been adopted. After having rapidly reviewed the principal characteristics of the purely special reflex actions and shown the general laws which preside over their mechanism and evolution, we shall successively examine in what respects the reflex cerebral actions approximate and in what they differ, as much under the double relation of the constitution of the organic substratum which serves for their manifestation as in the general dynamic conditions under which they show themselves outwardly.'

These expressions indicate very clearly the object the author has proposed to himself, and the method he has employed to attain it. They suffice to give an idea of the interesting nature of M. Luys's researches, and to show that after having, with his well-known minute carefulness, analysed the details of the anatomical structure of the nervous centres, he means to make evident, at least under one of its aspects, the synthetic assemblage of the functions of these organs and of the unity of the mechanism which, notwithstanding a great diversity of external manifestations, really rules all their action. The idea of reflex cerebral actions does not of right belong to M. Luys. It may be found expressed in a more or less explicit manner in a great number of recent works relating to the physiology and pathology of the nervous system, and is amongst those which in consequence of the current of modern physiological studies tend, as it were, to acclimatise themselves in the minds of observers, and which, at a given moment, are found to be part of their acquired notions, without their being able exactly to say where and how they have been acquired. It is therefore the more useful to formulate in a precise manner what every one feels in a somewhat vague way, as a rule, and to substitute in the minds of the profession a scientific theory and a rigorous method of demonstration in place of the more or less undecided notions of which they previously had an intuition.

The theory of reflex movements, produced by setting in action of the excito-motor power of the medulla, is too well known to need repetition. It is enough, like M. Luys, to call to mind that all reflex manifestations are divided into three stages: 1. A first stage, or period of incidence, in which incitation reaches the grey spinal matter; 2. A second stage or intermediary period, which corresponds to the moment when the excitement propagates itself, and gives rise to the activity of the nervous elements set in motion; 3. A third stage, or period of emission, which corresponds to the moment when the primordial element, continuing its evolution, shows itself outwardly, and makes its way along the centrifugal conductors.

The reflex movement results then from a transformation of force, in virtue of which the peripheral sensitive incitations are converted into motor-reactions, or, to put it in a still more concise way, the reflex movements are nothing else but sensibility transformed; and it must be added that, when the functions of the medulla are left to themselves, consequently removed from the influence of the brain, this transformation is automatic, unconscious, inevitable, and actually a matter of necessity. 'A frog

deprived of cerebral lobes when thrown into the water, must swim, just the same as a pigeon without cerebral lobes must fly.' (Onimus, Robin's *Journal d'Anatomie*, 1873, p. 546.)

Starting from these well-founded and now incontestable ideas, M. Luys sees in the structure of the cortical layer of the brain an assemblage of nervous elements, which, as much by their inherent characteristics as by their reciprocal relations, appear to him very analogous to the spinal elements and from the similarity of the material substratum, he believes himself authorised to conclude, and not without probability, the similarity of the action. In this hypothesis the sensorial impressions which, according to him, are centralised in the optic thalami would thence be transmitted to the most superficial submeningeal cortical cells, that is to say, to those which are the smallest and the most analogous to the small grey cells of the posterior cords of the medulla. These impressions would then diffuse themselves from one spot to another, through the superposed cellular zones, intertwined in each other, which constitute the different layers of the grey substance of the circumvolutions, down to the deepest of these layers composed of large cells, comparable to the large cells of the anterior horns of the grey substance of the marrow. 'And it would be as a sequel of this close conflict between the incident impression and the cerebral element, that the latter, transformed, purified, in some degree spiritualised, but nevertheless still preserving its original character, would give birth to the veritable psychic incitation.' This latter, in its turn, would continue its progressive evolution, and would change into emissions of voluntary motricity. The grey cortical substance would constitute 'an admirable sensitive-motor apparatus planned on the same type as the excito-motor apparatus of the medulla, and similarly destined to transform, as an essential piece of work, a sensitive incident impression into a reflected motor manifestation,' (p. 18). The movement which succeeds a psychic operation would also then be a reflex action of transformed sensibility, and this transformation would comprehend, as occurs in the case of the medulla, a period of incidence, a period of elaboration, and a final period of emission. Only, in the cerebral region, all the details of the operation are less simple than in the spinal region. The multiplicity of the cellular zones of the cortical layer; the variety of the anastomoses which connect together the various departments of the circumvolutions; the persistence of former impressions in the active or latent state, and the faculty which they possess of being evoked, and as it were revived by a kind of organic phosphorescence; the modifications which, according to the theories already set forth, by the author, would be imported into the motor incitations reflected along the white centrifugal cords, by the inclination of the cerebellous influx along the striated bodies, of the pons Varolii and of the bulb, are so many circumstances which singularly complicate the phenomenon, so that it finishes by being a more or less complex resultant in the production of which the essential nervous actions find themselves amplified, strengthened and metamorphosed in many various ways in the course of their evolutions. Nevertheless, however, there is always an inevitable, unconscious, and necessary relation of cause to effect between certain incident sensitive impressions and certain methods of motor reflection. And it is thus, for instance, that the in-

voluntary production of the assemblage of movements which express joy, grief, fear, and hope is explained. The same thing also holds of the co-ordinated movements of dancing, the different methods of musical execution, etc. In the visceral domain the same mechanism regulates the echo of the psychic impression on the circulatory, digestive, and generative systems. It gives the key to all which was formerly known under the vague denomination of sympathies. And all these phenomena are so ruled by a pre-established order, an automatic co-ordination, that man considered in time and space is always the same in this respect. In all ages of the individual or the race, in the child as in the old man, in our day as in the most distant ages of history and art, in our country as in the most remote regions of the globe, in the most civilised societies, and as amongst the most barbarous savage nations, everywhere the mode of expressing the sentiments is alike; everywhere to the incidence of the same sensitive impressions, succeeds the same assemblage of unconscious and involuntary motor-reactions. Parallel with these invariably uniform and absolutely general reactions, the same mechanism produces others, which are not innate in all men, but which in certain individuals acquire a kind of *locus standi* by repeated exercise, so that, by long prolonged habit, movements which were in the first instance voluntary are changed into a kind of unconscious automatism.

The retired soldier continues to make his military salute; the sailor walks with his legs wide apart even on *terra firma*; the barrister, when in lay costume, still retains the habit of trying to throw back the sleeves of his absent gown. And it is thus that the external type, corresponding by the attitude, the gesture, the fact, to any given profession, is formed.

The same mechanism is met with in many manifestations belonging to the domain of pathology. Sometimes it is a very lively impression which perpetuates itself, and by its persistence determines the continuation, either of a gesture or an idea, and thus engenders certain forms of catalepsy, or the monotonous and unchanging repetition of a maniacal action; sometimes it is the partial arousing of some sensitive impressions which, coinciding with the sleep of the other faculties, engenders the automatic manifestations of somnambulism; sometimes, even, it is a mental impression either of old or recent date, primary or revived, which determines the explosion of a convulsive fit of hysteria or epilepsy.

In a line with the study of habit, whether physiological or morbid, may be placed that of imitation. It is scarcely necessary to recall to mind the involuntary automatic manner in which certain acts, such as yawning and laughing, propagate themselves by imitation. In many other instances, likewise, crowds of people are unconsciously influenced in what they see around them; whence the likeness in the gestures, the expression, the general manner which is observed in persons constantly living together, the involuntary impulse owing to which in different ranks of society certain impulses, given by persons who for some reasons or the other are in a prominent position, propagate themselves.

The part played by imitation is not less marked in the pathological domain; it is to that which is due the propagation of convulsive epidemics or demoniac madness, and that of certain acts, such as suicide. Up to this time there has only been ques-

tion of what may be called general movements. M. Luys afterwards applies the same principles to the explanation of what may be termed special movements, and which are more particularly intended to serve for a method of expression for purely intellectual operations—by which he understands articulate language, written language, reading aloud, and the outward expression of artistic inspirations. As a prelude to the details of that study he aims at assigning a precise locality to these purely intellectual operations. Dr. Foville is, however, of opinion that before admitting, with M. Luys, that the seat of intelligence itself is thoroughly limited to the middle layer of the grey cervical substance, below the small superficial cells which are purely sensitive, and above the large cells, which are purely motor, it is only prudent to wait for the solution of many of the problems which experimental philosophy has not yet been able to remove from the region of the unknown. Notwithstanding these reserves M. Foville admits, with M. Luys, that 'the action of emitting desired articulate sounds, in a word, language, resolves itself into three successive periods, a period of incidence, a period of intracerebral propagation or intermediary period, and a period of emission or reflection.' (p. 115).

As to the detailed developments relative to each of these periods, though more complicated than those of which mention has been previously made, they have enough analogy with them not to require description here, and will be found fully described in M. Luys's work.

According to him, a great part is played by unconscious, or if it be preferred, mechanical automatism, in a series of acts which are, however, in the first rank amongst those which are considered as the free manifestation of a reasoning will. Here also, Dr. Foville thinks the writer has gone somewhat far, and he is scarcely inclined to admit, with him, that in the most eloquent speeches of the great orators, the succession of the different periods, the regular methods of rhetoric, the movements of passion or emotion, are but the 'inevitable or necessary expressions of the organisation of the human mind in the natural course of its evolutions' (p. 125).

There would be little left to the originality of the individual if all the above came from the simple mechanism of the species, and Dr. Foville recognises in this theory a certain co-efficient of exaggeration. He is also astonished that M. Luys has stopped short in his career, and that after having shown that the theory of spinal reflex movements can in a great measure be applied to movements which have not their starting-point in the brain itself—that, in a word, the as much generalised as special movements (speech, writing, drawing) are in great part transformed sensibility,—he has not been able to extend the same explanation to many intellectual operations not followed by movements, that is to say, to the production of the thoughts themselves.

Are not the conceptions of our mind as much in the normal as in the pathological state the result of the reflexion of incident sensitive excitations?—in other terms, are not the ideas themselves sensibility transformed? This manner of looking at the question makes it more easy to understand the philosophic aphorism, '*Nihil est in intellectu quod non prius fuerit in sensu*,' than any other. Applied to mental pathology, it affords the best explanation of madness with hallucinations. The hallucination in fact being a perversion of sensation, gives an incident ray

tainted with error, and from that time the conception which follows it, like a reflected ray, is itself erroneous and insane. And as these patients labouring under delusions, by the side of their perverted or false subjective sensations, continue to perceive objective sensations in a natural and normal manner,—that is to say that they experience at the same time imaginary and false sensations and real and exact ones,—so their intellectual conceptions, according as they correspond to the one or the other of these kinds of sensation, are also sane or insane. Hence the same person appears mad or sane according as the ideas he expresses result from the transformation of a morbid or a healthy act of sensibility, which gives the key to partial madness, so that, if it be true as Michéa has said, that hallucinations are a kind of delirium of the sensations, it would be no less correct to consider intellectual insanity itself as a kind of convulsion of the mind, that is to say, a morbid manifestation of sensitive-motor or reflex power of the brain; as convulsions are a morbid manifestation of excito-motor or reflex power of the medulla. It might also be said that in the brain, the transmuting organ of sensibility, that is to say, the reflecting mirror, is likely to undergo organic or dynamic changes of which we do not know the nature, but can only record the results; sometimes, for instance, the mirror acquires an excess of polish and brightness, so that the least incidents of sensibility are reflected with an equally excessive promptitude and intensity; sometimes on the contrary, the mirror becomes dimmed and darkened, and all the incident rays are extinguished in it and are absorbed without giving off any reflection. In the first cases, it is easily understood that the psychic and motor reactions are multiplied and tumultuous; they scatter themselves in every sense of the word, succeed each other so rapidly that it is difficult to seize them in transition, which constitutes in mental pathology, the symptom called maniacal excitement with all its shades, from simple mobility to uncontrollable agitation. In the second case psychic and motor reactions are nullified, or more or less weakened, which constitutes all the gradations of melancholy depression, from simple sadness to complete stupor. If these modifications of the mirror be stable and permanent, the forms of mania and chronic melancholia are of an uniform type; if they succeed each other alternately, at shorter or longer or more or less regular intervals, there will be that series of fits of excitement and depression, the succession of which characterises mania of both forms. The different forms of stupor may also be better understood if considered from this point of view. It has been already said that the mirror has become dimmed and darkened, and receives the incident rays without reflecting them. But the darkness may be either superficial or deep. Borrowing M. Luys's hypothesis on the stratification of cortical zones, the incident sensibility may be extinguished and absorbed on reaching the layer of the small sensitive superficial cells, and then the cortical functions are really suspended; no sensation is felt, no ideas are formed, the stupor is real or complete. On the other hand the darkening and the absorption may only take place on the outward surface of the mirror, that is, on the layer of the great motor cells; in this case the sensibility may remain exquisite, the formation of ideas be active and distressing, the motor reaction alone may be at fault; the patient then presents the spectacle of

melancholy with stupor, in which, according to M. Baillarger's fine work, the apparent mask of insensibility may conceal an excessively intense, melancholic and hallucinative insanity.

M. Foville concludes by designating M. Luys's work as one of the most interesting books to be met with, both from the thoughts set down in it and those which it suggests. It is illustrated by plates, some photographed from nature and others to scale, and intended to show the intimate correlation of the reflex movements of the brain with the better known movements of the spinal marrow.

MEDICINE.

MCBRIDE ON THE COMPLEMENTARY PARTS OF DISEASE.—In the *Cincinnati Lancet and Observer* for April, 1875, Dr. Alexander McBride says that by observing apparently trivial symptoms we may be led to anticipate the inroad of serious disease. By 'complementary parts of disease' he means those symptoms and signs which are sure precursors of something to come, or which may with certainty be expected to follow that which has already appeared.

Stoppage of the lochia may, for instance, be regarded, as a rule, as the precursor of a grave inflammatory disease. There is a similar relation between 'heat-rash' (*lichen tropicus*) in children, and *cholera infantum*, the latter of which very frequently appears a few days or weeks after the disappearance of the former. A woman complains of paroxysms, of palpitation, and dyspnoea, dizziness and general discomfort when she knits or sews, belching, flatulence, rumbling of the bowels, pain near the apex of the heart, and at the middle of the left arm, hysterical convulsions, and numerous other distresses. She has also a troublesome cough and soreness all over the chest, and there is great tenderness over the cervical and dorsal vertebræ. Such a case has been treated sometimes for consumption, and sometimes for spinal disease. The entire train of symptoms is caused by leucorrhœa, or by some uterine displacement, which may have been in existence some years. It is at least certain that by curing the leucorrhœa and malposition of the uterus, if any exist, the whole series of reflex ailments disappear. And again, a woman near middle age, complains of aphonia, loss of strength, sweating. The urine is pale and copious. The symptoms are not constant, but are frequently repeated without any apparent provocation. An examination will reveal a large and flabby uterus. The case is relapsed uterus, and a proper use of ergot will cure it promptly. Iron may follow. A woman presented herself with an obstinate eczema covering one side of the face. There were also found severe dysmenorrhœa, narrowing of the cervix, and great irritability or cervicitis. The proper treatment of the latter conditions cured her face, and the cure was permanent. Endometritis is sometimes accompanied by pain in the hip, which has been mistaken and treated for coxalgia. A persistent headache, which is independent of fever or gastric derangement, is frequently followed by an eruption of some sort. Cutaneous eruptions are complementary of internal disease. Acne is generally supposed to be connected with some kind of sexual irregularity; but those who suffer from it are ravenous eaters. This fact points to the stomach

and duodenum as the seat of the disease. Arsenic probably cures cutaneous diseases by curing the internal diseases upon which they depend. Herpes zoster is clearly the complement of something internal. Cases are met with in which a mild pneumonia, or pleuro-pneumonia, or bronchitis, or all three of them is associated with a rash resembling scarlatina and measles. These cases are seldom severe when the rash co-exists, and require very little treatment. Measles is the completion of a disease which was originally a slight congestion of the lungs, or more especially of the bronchial mucous membrane, and the eruption of scarlatina bears a similar relation to the region of the throat. Tinea capitis of children, if dried up, is generally followed by hydrocephalus, encephalitis, cerebritis, meningitis, or some such disease. The best treatment is to apply a blister all over the scalp. 'It is not necessary to shave the scalp and apply a plaster. Cover the scalp with cantharidised oil or tincture of cantharides, and then cover with oiled silk, a greased cloth, or green leaves, and you will have blister enough.' In syphilis, where there are copious manifestations of the disease on the skin and subcutaneous tissue, the bones and other internal parts almost wholly escape. When general rheumatism and endocarditis co-exist, the cardiac complication is less grave than when it exists primarily, or follows the disappearance of the rheumatism. The phrenzy which is liable to follow is but a symptom of endocarditis. A vesicular eruption or punctate rash frequently accompanies rheumatism, and the violence of the disease appears to be moderated by its appearance. The beneficial effect of blistering appears to result from 'the restoration of the lost element—the complementary part.' A continuous recurrence of fugitive lancing pains in various parts of the body (chiefly in the fibrous tissues) is indicative of cardiac disease, generally organic, but sometimes functional. In other words, these pains are complementary of cardiac disease.

[The frequent co-existence of herpes labialis and pneumonia may be mentioned as a good example of the associations of disease. Such cases are very common in this district. If a person has smart feverish symptoms along with herpes labialis it may at once be predicted that the case is one of pneumonia and that convalescence will be ushered in on the sixth day of the disease, more especially if the patient is under thirty years of age. The pneumonia is sometimes so slight that it is necessary to make a careful physical examination before the disease can be detected. On the other hand there is very high delirium, even in slight cases: so much so that I have known such cases to be treated for encephalitis. Cases of what, from the absence of a rash, must be regarded as ordinary sore throat are frequently followed in a fortnight by acute rheumatism. It is quite possible that such cases are suppressed scarlatina. I have, however, noticed the association between the two diseases so frequently that I have on more than one occasion been able to foretell to a day the advent of rheumatic fever. The correlations of psoriasis, bronchitis, and gout will readily occur to every medical man.—*Rep.*]

JAMES ROSS, M.D.

JÜRGENSEN ON ACUTE PNEUMONIA.—One of the later volumes of Von Ziemssen's *Handbuch* contains a treatise on pneumonia by Professor Jürgensen, of Tübingen, who has for many years made a special study of the disease; and his views as to its nature and treatment deserve to be known in

England, though they are far from being generally accepted by German physicians.

He is a strenuous upholder of the theory that acute fibrinous pneumonia is not a local, but a general disease, and gives the following reasons for holding this opinion. It has not the same geographical range, nor is it most frequent at the same seasons of the year, as bronchitis, which is confessedly a local disease, and when individual cases come to be examined, it is found that external causes (cold in particular) have a very doubtful influence in its production. By its anatomical character (fibrinous exudation into the alveoli) the disease differs from all other forms of pulmonary inflammation, whether natural or produced experimentally. There would appear to be no constant proportion between the local state and the pyrexia, extensive pulmonary consolidation being often accompanied by very moderate amount of fever, and *vice versa*; moreover, the fever runs a certain definite course, beginning before any local mischief can be detected, and ending before the inflammation has subsided. Jürgensen considers pneumonia to be most akin to acute rheumatism and cerebro-spinal meningitis, both non-contagious diseases, but which he looks upon as produced by some external cause of infection similar to that of malaria.

If this be a correct view of the disease, it follows that the physician has not so much to attempt to 'strangle' it, as to preserve life until nature can effect a cure. Now the degree of danger to life depends less upon the potency of the pneumonic poison than upon the patient's power of resistance, in which respect the disease contrasts strongly with such maladies as diphtheria or plague, where the activity of the virus seems to be the essential element of fatality. Our author teaches that the one cause of death in pneumonia is insufficiency of the heart's action, to which both the local mischief and the pyrexia tend, although in themselves they would not prove fatal; for the pneumonic exudation disturbs the circulation through the lungs, and so throws more work upon the right ventricle, while the fever overworks the organ by increasing the frequency of its action, while (as Zenker and Liebermeister have shown) it directly tends to produce degeneration of the cardiac muscular fibres. Since, then, nothing can be done to remove the exudation matter in the lung, Jürgensen considers that the aim of treatment should be to diminish the amount of fever; he rejects digitalis, veratria, and tartar emetic, which he considers to have too depressing an effect upon the heart, and employs only cold baths and quinine.

The baths are administered in every case of pneumonia, whenever the temperature reaches 104°; ordinary cold spring water is used, and the patient is left in the bath from five to seven minutes, according to the effect produced upon the temperature of the skin. In severe cases they may be frequently repeated, and when the patient is very feeble, or the temperature is not so high, luke-warm water may be used, the bath being then continued for from twenty to thirty minutes. In all cases an alcoholic stimulant is given before and after the bath, the quantity being regulated by the state of the pulse. The bath is usually given in the morning, and in the evening the patient takes three grammes of quinine dissolved in water with hydrochloric acid; this will keep the temperature down for at least twelve hours, the thermometer usually falling from 3 to 4·5 degrees for

the first five or six hours after the dose has been taken. If the pyrexia is greater than usual the dose of quinine is increased; in severe cases our author has ordered five grammes (about seventy-five grains) of quinine at one dose, and has never observed any evil results, the pulse (on the contrary) improving in fulness and strength as the temperature falls; he also claims for the quinine that it relieves the insomnia from which pneumonic patients so frequently suffer. Whatever dose may have been given, it is repeated every other night, this being found quite sufficient to keep the fever in check. His patients are allowed a liberal diet, usually a little meat and bread-and-butter two or three times a day, and, in bad cases, he is not sparing in administering strong broth, eggs, and wine.

He quotes the returns of the Basle Hospital, as compiled by Fisser, to show the success of his treatment; they appear to prove that while the mortality under the 'school plan of treatment' (whatever that might be) was 25 per cent., it was reduced, during the years 1866-71, when his 'anti-pyretic' method had been adopted, to 16.5 per cent.

[As to the harmlessness of large doses of quinine, it may be interesting to remark that Leibermeister, who treats enteric fever on nearly the same general principles, always gives quinine in doses of twenty-four to forty-five grains, and sometimes more, and that he has never seen any harm result from these, or even larger, doses.—*Rep.*]

J. R. GASQUET, M.B.

LEARNING ON THE DIAGNOSIS OF MITRAL REGURGITATION: THE CAUSE OF THE FIRST SOUND OF THE HEART.—Dr. James F. Leaming, in the *New York Medical Record*, April 3, holds that Dr. Camman has demonstrated by pathological investigations that the signs of mitral regurgitation, as generally taught—namely, the presence of murmurs at the apex of the heart, denominated blowing, sawing, rasping, etc.—are not reliable; but that the true invariable sign is a murmur of an entirely different character—a soft murmur, a friction murmur, such as is heard naturally when fluids are forced through comparatively small openings, and is heard behind, between the seventh and eighth vertebrae, close to the spine. This is the only sign certainly diagnostic of mitral regurgitation. Dr. Leaming goes on to say that, such being the case, the mechanism of the first sound of the heart becomes a matter of high importance in the diagnosis of functional as well as organic murmurs. After giving the theories ordinarily held as to the cause of the first sound of the heart, the writer says: 'As none of these theories seem to accord with all those conditions present in the organ, especially with the acoustical conditions, he had been impressed with the truth that they do not give satisfactory evidence of the real origin of the first sound, and that we must direct our attention to the heart itself for the new proof. When we come to examine the heart itself, we find within it a musical arrangement, a drum-like expansion, to which are attached tendinous chords that are held in position through the intervention of muscular fibres. It seems incredible that such admirable conditions for producing sound-vibration should have been so long overlooked by so many able observers as the most probable cause for the first sound of the heart. That the first sound is produced by the vibrations of the *chordæ tendineæ* is a reasonable position to take; and if the doctrine can

be proved by pathological evidence, it will very much simplify our investigations. If plastic lymph be excluded upon the surface of the valves, and at the same time the *chordæ tendineæ* are shortened and thickened by the presence of plastic lymph, or glued down upon the surface of the valves so as to prevent vibration, and then if the first sound is altered or murmurs abolished, it must be that the proof is sufficient that they are the parts directly concerned in the production of the first sound.' He also says: 'Experiments have been performed by various experimenters, in which it has been shown that when blood is arrested from entering the cavities of the heart all sounds are extinguished, and that they return with the admission of the blood, and also that the first sound is produced when only a small quantity of blood is permitted to enter the ventricles. The fact that the first sound disappears under these circumstances, and all murmurs connected with the first sound also disappear, is to be regarded as an indication of sound-vibrations, and is equally convincing as the hooking up of the curtain of the aortic valve is proof of the mechanism of the second sound of the heart.'

J. MILNER FOTHERGILL, M.D.

DROUET ON ALCOHOLIC EPILEPSY.—Dr. Drouet has collected a number of cases of epilepsy occurring in drunkards, in whom no other cause for the epileptic attacks could be found than acute or chronic drunkenness. Of 442 male drunkards 45 were epileptic; of 87 female 9 were epileptic. Among drunkards below thirty, the proportion of epileptics was 1 in 15; between 30 and 50 it was 1 in 8. Epileptiform attacks very rarely occur in acute alcoholism. Drouet reports one case at length, but in that the fit occurred while the patient was at the guard-house, before he came under observation.

The cause of the attacks in acute alcoholism the author seeks partly in the idiosyncrasy of the patient; partly in the chemical change undergone by the alcohol in the organism—the transformation into oxalic or carbonic acid being more likely to cause convulsions than the others; and partly in the pathological change, the amount and position of cerebral congestion, and the occurrence of small cerebral hæmorrhages. With regard to the influence of the nature of the liquid ingested, the author considers, in spite of the experiments of Dr. Magnan showing that alcohol never, and absinthe frequently, produces convulsions in the lower animals, that in the human subject alcohol is the main cause and absinthe very rarely gives rise to epileptic seizures.

In chronic alcoholism convulsion most often follows an unusually great excess; sometimes it comes on in the course of continued intemperance, without there having been actual drunkenness or delirium tremens, and in other cases it attacks those who are debarred from drink in asylums, sometimes after long-continued abstinence.

Under the head of pathological anatomy many lesions are enumerated, none of which, the author is careful to say, can be considered characteristic.

The prognosis is not good. Of the 54 cases 3 died (two from causes foreign to the malady), 12 are considered incurable, and the rest recovered in periods varying from 1 month to 2 years.

The treatment was bromide of potassium or arseniate of soda, with abstinence from intoxicating drink and regular living.

[Epilepsy is a most difficult pathological problem. Alcoholic epilepsy must be an exceedingly difficult

one. Great credit is due then to any one who takes pains in trying to clear up our difficulties on the subject. The above abstract of M. Drouet's paper will, we think, suffice to draw the attention of English readers to what he has written, and lead to a careful study of the original paper by those specially interested.—*Rep.*] J. HUGHLINGS JACKSON, M.D.

ALLING ON INJECTIONS OF MORPHIA.—Everything relating to the study of hypodermic injections is deserving of attention at the present time, when this therapeutic process is likely to be more used every day. Although the question of pain induced by the liquid of the injection at the moment it penetrates into the conjunctive tissue, has long been overlooked, yet it none the less deserves attention, since it is enough to prevent many timid people from using a plan of treatment from which the best results may be expected. In relation to this point Dr. Alling communicates a short note to the *Alger Médicale*, no. 24, in which he studies the nature of the liquids containing cherry-laurel water. He has tried on himself solutions of morphine containing cherry-laurel water in different proportions. Solutions of morphine in pure cherry-laurel water are extremely painful, but when the solution only contains a fifth part of cherry-laurel water the pain is very slight. He recommends this formula: Chlorhydrate of morphine, one decigramme; distilled water, four grammes; cherry-laurel water, one gramme. He is not yet in a position to say if this proportion of cherry-laurel water is sufficient to preserve the solution.

SURGERY.

MARTELLI ON A CASE OF EXTIRPATION OF THE LARYNX.—In a communication to the *Gazzetta delle Cliniche*, for March 9, Dr. E. Martelli, surgical assistant in the hospital at Novara, records a case in which the operation of extirpation of the larynx was performed by Professor Bottini.

The patient was a countryman, aged thirty-four, who had for some time suffered from attacks of orthopnoea, from a mechanical obstruction in the larynx. In August, 1874, the dyspnoea was so urgent that laryngotomy was performed in the crico-thyroid space; this relieved him, and a tube was left in the opening. In October, Professor Bottini was called to see him in consultation with Dr. Perassi. The galvanic cautery was applied with the object of freeing the larynx from the morbid growth which

occupied it; but the larynx remained impervious to air. Attempts were then made to dilate the parts by means of laminaria tents; but, though repeated several times, they were not successful. The patient was accordingly admitted into the hospital, and Dr. Bottini extirpated the larynx on February 6 of this year. Chloroform was not given.

An incision about five centimètres (nearly two inches) in length was made from the hyoid bone down to the artificial opening in the larynx; then, by means of horizontal incisions to the right and left, two flaps were formed, which were dissected up and turned outwards. The anterior part of the larynx was then carefully laid bare, the edges of the wound being held apart by hooks, and the connection between the larynx and the œsophagus was severed by means of the fingers and blunt instruments. This part of the operation was rather difficult, in consequence of the shortness and thickness of the patient's neck, and of his continued attempts to expectorate. These attempts were so violent that the patient, three or four times during the operation, expelled the cannula with the sputum. It was found impossible to remove the larynx by at once cutting it free from the trachea below and the hyoid bone above, and the process had to be suspended several times to allow the patient to relieve himself by coughing up the mucus and blood, which escaped into the trachea notwithstanding all the care that was used to prevent it. Several arteries, especially the two superior laryngeal, were tied, and the galvanic cautery was applied to others.

The subsequent history of the case shows that on the 11th erysipelas set in, but disappeared by the 21st, from which time the patient's temperature did not exceed 98.9° Fahr. and the pulse 80. He was on the latter day able to swallow fluid and semi-fluid food; the paroxysms of cough had become rare and slight; the wound had healed, for the most part by the first intention notwithstanding the erysipelas; he slept fairly well at night; and altogether his condition was promising.

No account is given of the nature of the disease for which the operation was performed; but Dr. Martelli intimates that a complete account of the case will be published by Professor Bottini.

A. HENRY, M.D.

GOLDSCHMIDT ON A CASE OF FOREIGN BODY IN THE NECK.—Dr. Eman. Goldschmidt reports (*Medicinisch-Chirurgische Centralblatt*, no. 14-15, 1875), a case in which the blade of a bread-knife was removed from the side of the neck, where it had remained for two years and a half. The patient, who was a soldier, first presented himself in May, 1873, with his head bent forwards and to the left side, and immovably fixed in this position. The soft parts over the mastoid process of the right temporal bone were much swollen, and in this region was a round ulcer having an unhealthy looking surface. The right auditory meatus was filled with thick and ill-smelling pus. This condition was supposed by the patient to be the result of an accident which happened to him whilst felling timber, in which a heavy piece of wood fell upon the side of his head. Dr. Goldschmidt diagnosed the case as one of necrosis or caries of the mastoid process following acute periostitis. There was supposed to have been some absorption of the mastoid process, and a probe could be readily passed from the surface of the ulcer into the right auditory meatus. The

corresponding membrana tympani remained intact, and hearing was good. The integument in the neighbourhood of the ulcer was red and inflamed, and the glands on the right side of the neck were hard and swollen; just behind the lower angle of the lower jaw was a small jagged opening, from which a considerable quantity of pus could be pressed out. In December of the same year the patient again applied to Dr. Goldschmidt, and stated that he could feel with a probe a loose rough body below the ulcer behind the right ear. The general health had been much impaired, and an abscess of the size of a hen's egg had formed on the right side of the neck. An attempt was made to remove the rough and movable body from over the right mastoid process, but in consequence of free hæmorrhage, and severe pain complained of by the patient, the operation was not completed. On a second attempt ten days later, the body was removed, and to the astonishment of Dr. Goldschmidt proved to be a portion of a knife-blade, which portion was two inches seven lines in length, and seven lines in width at the widest part. The patient afterwards stated that in June, 1871, during a scuffle in an ale-house, he had received a wound on the right side of the neck just behind the ear. This wound bled freely at the time, and remained painful for some weeks. After the removal of this foreign body the movements of the head became free and painless, the profuse suppuration gradually diminished, and finally ceased, and the glandular enlargement and cicatricial thickening were slowly reduced.

BEELY ON THE HEMP AND GYPSUM SPLINT.—Dr. Beely, in the *Berliner Klinische Wochenschrift*, no. 14, 1875, directs attention to a new kind of splint, which during the past twelve months has been extensively used by Professor Schönborn, of Königsberg. The materials used in the composition of this splint are heckled hemp, the fibres of which must be arranged as parallel as possible, and gypsum powder, such as is used in the ordinary gypsum bandage. Bundles of the hemp, each of about the thickness of the little finger, and of a length corresponding to that of the part to be covered, are dipped in a mixture of gypsum and water, and then applied side by side over the surface of the limb, which surface should have been previously oiled or covered by flannel. These splints speedily become dry and form a hard casing, closely applied to the whole surface of the limb. They can be readily strengthened by the subsequent addition of other bundles of hemp saturated in the same way by gypsum and water, and may be rendered waterproof by painting over their surface an alcoholic solution of shellac. When it is necessary to apply a splint of this kind to the posterior surface of the leg or thigh, and the patient cannot turn over so as to place this surface uppermost, the bundles of hemp, after mixture with gypsum, should be kept in contact with the limb by means of a flannel bandage. The advantages which this is alleged to possess over other fixed splints of different composition are its cheapness, the facility of its application, its durability, its porosity, and the rapidity with which it becomes dry and firm. Dr. Beely thinks that it would prove a very useful application when a patient suffering from fracture or gunshot-wound has to be moved, and that gangrene would be less likely to occur than from the use of the ordinary gypsum splint. In Professor Schönborn's practice this form of splint has been applied in about fifty cases, and generally

with good results; the injuries and diseased conditions thus treated having been simple and compound fractures, articular affections, injuries to tendons, and deep wounds of soft parts in limbs, rachitic deformities and club-foot, and flat foot.

W. JOHNSON SMITH.

MATERIA MEDICA AND THERAPEUTICS.

DUJARDIN-BEAUMETZ AND BLACHE ON THE PART PLAYED BY THE PHOSPHATES IN THERAPEUTICS.—At the meeting of the Paris Société de Thérapeutique, on March 21, M. Dujardin-Beaumez presented a report (*Bulletin Général de Thérapeutique*, April 15, 1875) on an essay by Dr. René Blache, based on cases of albuminuria and diphtheria in which phosphate of lime seemed to have been of great value. M. Blache is of opinion that albuminuria and diphtheria are two cachectic conditions having this point in common, that the albumen would have a tendency to eliminate itself in both diseases either by the urine or the surface of the inflamed mucous membrane. The action of phosphate of lime would consist in favouring the assimilation and the passage of this albumen in the form of cells and fibres of all kinds, and would then oppose itself to its elimination. Without stopping to consider M. Blache's theory, M. Dujardin-Beaumez thus sets forth the state of the question of the influence of calcareous phosphates on the economy.

Owing to the progress of animal chemistry, it has been decided that all the constituent parts of the animal economy are composed of immediate principles, with which are sometimes associated mineral substances; these being alkaline phosphates (soda and potash) or earthy ones (lime and magnesia). As a result of these analyses certain laws have been established which it is important to know and which may thus be summarised. 1. In all the constituent parts of the animal economy, the bones excepted, the proportion of alkali (soda and potash) is always four times more considerable than that of the earthy parts (lime and magnesia). 2. In the fluid portion the soda predominates; in the solid parts, the potash. 3. In the liquid portions, the alkalies are in larger proportions than the phosphoric acid; whilst in the solid portions the phosphoric acid prevails over the alkalies. These laws once known, it was then thought that the phosphates, thus forming part of all the constituent substances of our economy, became bodies indispensable to our existence; and Choissat's experiments seemed to give warrant for this view of the case. Since then, experiments, taken up again by Kämmerich, Voit, and other experimenters, have shown that the action of the phosphates had been much exaggerated, and that, as a rule, they only played the part of simple aliments. M. Dujardin-Beaumez does not offer any decision on the question of the absolute necessity for phosphates. He thinks they are useful; but he asks himself, in the latter case, how may the dose of these phosphates be administered and increased? He then shows, by the precise experiments made in Germany, and of which M. Samson has given a very exact abstract (*Bulletin Gén. de Thérapeutique*, vol. lxxvii.), and by M. Chéry-Lestage's memoir (*Ibid.* vol. lxxvii.), that the only way of administer-

ing phosphates is to employ those which Nature has already assimilated—bran-bread, and beans of different kinds. Whenever it has been wished to augment the dose of phosphate, by adding soluble or insoluble phosphates to the food of animals, these phosphates have only passed through the economy without effecting any lodgment there. However, beneficial results seem to have been obtained from soluble phosphates in certain affections; and these successes M. Dujardin-Beaumetz explains by the precipitation of insoluble phosphates, as M. Mialhe demonstrated a long time since, and M. Cauler at a later period (*Bulletin Gén. de Thérapeutique*, vol. lxxvii.), and by the favourable action of hydrochloric and lactic acids on the digestion. As to the special cases pointed out by M. Blache, their explanation is rather to be found in the acid action of the soluble phosphates than in the phosphates themselves. Bright recommended acid treatment in chronic diseases of the kidneys a long time since.

CLARK ON FASHION IN MEDICINE.—Dr. Dongan Clark, in an address to the graduates of the Indiana Medical College, where he is Professor of Medicine (*Cincinnati Lancet and Observer*, April, 1875), says, 'Thirty years ago the lancet was used in perhaps nine cases out of every ten visited by the physician. To an equal proportion some preparation of mercury was administered. Now, I apprehend that the ratio is reversed, and that the physicians bleed and mercurialise no more than one in ten of their patients. Most of them, indeed, allow their blood-letting instruments to remain at home altogether, and grow rusty in total neglect. The human system will bear very considerable losses of blood with impunity—as is evinced in *post partum* and other hæmorrhages—and I do not presume to criticise with any severity the proceedings of our immediate forefathers in the profession. Very few persons were actually bled to death by physicians, even in the days when phlebotomy was most prevalent; yet it can scarcely be otherwise than true that more harm than good resulted from this indiscriminate depletion. A patient in Philadelphia was very ill of pneumonia; he was subjected to repeated and large venesections, and after several days the physician reported that he was cured of pneumonia, but was dead of debility. Whether death by debility is easier and better than death by pneumonia, I am not prepared to say. In our day, as already intimated, the lancet has fallen into almost total disuse. It may well be questioned whether, at the present time, the reaction against blood-letting is not too strong, and whether we are not allowing our patients to suffer from the too unfrequent, as they formerly suffered from the too frequent and excessive, employment of the lancet. As regards mercury, there can be no doubt that the generation of physicians immediately preceding our own employed it in excessive quantities, and sometimes to the injury of their patients. The injuries so produced have inspired the public mind with a prejudice against the drug; a prejudice so strong, indeed, that many patients now will steadfastly resist its administration even in cases where it would do them immense benefit. Mercury, like alcohol, has undoubtedly its legitimate use as well as its abuse; and every one of you has met with cases in which it could not be effectually substituted by any other drug in the pharmacopœia. Yet of an equal number of persons who have taken calomel and lobelia respectively,

a much greater proportion have perished from the latter drug than the former. If one has slain its thousands, the other has slain its tens of thousands. In hundreds of homes in Indiana lobelia is kept as a domestic remedy, and administered, without fear and without the advice of a physician, by good mothers to their sick children; while the same mothers would dread to administer a dose of calomel, even by a physician's direction, as they would dread a serpent's bite.'

WADE ON BROMHYDRIC ACID.—In the *Peninsular Journal of Medicine*, February, 1875, Dr. De Witt C. Wade gives an account of the uses of this agent and his mode of preparation. He commences by saying that in many cases we introduce a salt into the body in order that its acid may be set free in the stomach. Thus we give iodide of potassium to introduce iodine into the system. If iodide of potassium were as stable a salt as chloride of sodium, it would surely be prescribed, and never, intelligently, for the purpose of realising the specific effects of iodine. But as long as iodide of potassium is decomposed and the iodine liberated, why not continue to use it? Because it is unscientific to make unnecessary use of the stomach as a chemical laboratory when we know that its operations are variable, especially during sickness; because we never know how much of the halogen is liberated, and as a consequence we will either have an excess of it or of the salt; because if we have any way to know how much of the halogen will be necessary to affect our patient as we desire, it is unscientific to give more or less; at least we consider it so with most drugs, because if the salt is absorbed and eliminated without decomposition, as may occur in some conditions, the result will be a disappointment that will be very mysterious to most practitioners. The effect of bromhydric acid is to modify the cerebral action of quinine and morphia. In cases where they cannot be tolerated alone in such combination they act very beneficially. In some respects, however, effects may be expected from the acid that are not obtained with the bromides. For instance, it appears to affect the stomach similarly to the other mineral acids—increasing the appetite, aiding digestion, and acting as a general tonic—therefore having a wide range of applicability. Bromine is known to be a powerful antiseptic, and its hydrogen acid, combined with quinia, cannot be too highly extolled in septicæmia. The acid is a grateful refrigerant and sedative, administered with syrup in fevers, with which, among other combinations, may be made the bibromide of mercury as an alternative. In fact, the acid alone is a powerful alternative. The ordinary method of preparation produces an article expensive to make and liable to spoil by keeping. Dr. Wade's plan is as follows. One equivalent of bromide of potassium, two equivalents of tartaric acid, and only sufficient water to dissolve each. Mix the solutions and let it stand in ice-water twelve hours; decant and add water to make a fluid ounce for each eighty grains of bromine. The bitartrate of potassium resulting is but slightly soluble, and is an impurity that does not in any way affect the therapeutic properties of the bromhydric acid. Thus prepared, bromhydric acid represents ten grains of bromine to each fluid drachm. It is of pale straw colour, and very acid. The medium dose is half a drachm, well diluted.

OBSTETRICS AND GYNÆCOLOGY.

MARTIN ON A CASE OF RICKETY OBLIQUELY CONTRACTED PELVIS, THE RESULT OF SUPPURATION OF THE BODIES OF THE LOWER LUMBAR VERTEBRÆ: CÆSAREAN SECTION.—At the meeting of the Gynæcological Society of Berlin, on October 6, 1874 (*Berliner Klinische Wochenschrift*, no. 51), Dr. E. Martin brought forward a case which occurred in a woman, aged thirty, who had been ill when two years old, and from between the ages of eight and fourteen had suffered from an 'open wound' opposite the left sacro-iliac articulation, from which there was removed, on three occasions, large splinters of bone. With the appearance of menstruation the wound closed, and she remained healthy but weak. The contraction of the pelvis was great, with a very narrow and straight pubic arch. The transverse diameter at the outlet measured only 4 centimètres (1·4 inches). The external measurements of the pelvis are given—not the internal. The external conjugate diameter was only 21 centimètres (8·2 inches) and the entire circumference was only 77 centimètres (30½ inches). The head presented, but on the rupture of the membranes a hand could be readily felt). The labour began at 3 P.M. At 10 P.M. the pains being good, with the anterior lip swollen, and the foetal heart-sounds being still distinct, Cæsarean section was performed. An incision, 11 or 12 centimètres (about 4·7 or 4·8 inches) long, was made in the linea alba, extending to the left of the navel for about 0·8 inch above it. Hæmorrhage was slight, but became profuse on the uterine incision striking the margin of the placenta. An incision about 11 centimètres (4·6 inches) long was made in the uterine walls, purposely more towards the fundus than the cervix. The child was extracted breech foremost, in order to prevent any laceration of the uterus towards the cervix; a small rent did take place at the fundal end of the incision. The foetus was removed without any difficulty. The child weighed 3,180 grammes (7 lbs.), and measured 49 centimètres (about 19½ inches). After rapid removal of the placenta, the hæmorrhage from the uterine wound, which was rather profuse, was easily stopped by means of fourteen catgut sutures. The abdominal cavity was most carefully cleaned out with prepared sponges. The abdominal walls were closed with iron wire sutures, which were passed through the peritoneum, short strips of adhesive plaster were applied between them. A compress soaked in a solution of carbolic acid (1 per cent.) was laid on the wound, and over this cold water, but later on ice-cold applications. The progress of the puerperium was not a particularly disturbed one. The sutures were in part removed on the twelfth and in part on the fourteenth day. She got up on the seventeenth day and left

the hospital on the twentieth; when seen three weeks afterwards, she was perfectly well.

Dr. Martin added the following critical remarks to this communication.

1. He extracted the breech, which was lying at the fundus, first of all, because he had found from experience that the not unfrequently laborious removal of the head, situated at or in the lower segment of the uterus, easily leads to a lateral rent in its thin muscular walls. A tear in this situation is, on account of the ascent of the abdominal walls during the latter period of gestation, more difficult of closure than one at the fundus; and the danger of secondary hæmorrhage (perhaps with consecutive suppuration) is great.

2. In dangerous hæmorrhage from the uterine wound, where cold compression, etc., do not succeed in arresting it, the most reliable means is suture, for which catgut is the most suitable material. It admits the possibility of absorption, whilst the author has seen, for example, silk sutures apparently eliminated by the rectum with signs of irritation. Catgut has its drawbacks, besides its tendency to break. In one case of Cæsarean section, the suture in the uterus became untied; in another of ovariectomy, the pedicle slipped out of the catgut noose; and in both the results were fatal.

3. The peritoneal cavity should be cleansed with the greatest care by unused sponges. The neglect of this precaution can not with certainty be retrieved either by supplementary suction of the abdominal cavity, although in some cases of ovariectomy this has succeeded admirably, or by drainage into the vagina through Douglas's pouch.

4. Great weight was laid upon the after-treatment, especially the attendance and the withholding of food and drink at first, and the application of remedies only when there is a definite indication for their use (for example, hypodermic injections of morphia). The external wound is treated with compresses of 1 per cent. of carbolic acid lotion, then with cold compresses. The ice-bag is rarely applied. Any artificial means for an early emptying of the bowels is not required. [Sir James Simpson always advised the abstraction of the arm and head first, on account of the danger to the life of the child from grasping of the child's neck through contraction of the uterus.—*Rep.*]

CASANOVA ON THE EXCITATORY ACTION OF THE DISULPHATE OF QUININE ON THE MUSCULAR FIBRES OF THE UTERUS.—The following is an abstract of two letters from Dr. P. Casanova to Dr. Rossolo Griffini, which appeared in the *Annali Universali di Medicina* for November, 1874. The observations he considered of interest, as bearing upon the doctrine of Dr. Monteverdi.

B. M., aged twenty-three, strong, had for five months been suffering from a kind of intermittent fever of the quotidian type, for which she had employed no remedies. She was first seen on February 12, 1874. A careful examination showed all the functions normal; no disease except a slight hepatico-splenic engorgement, accompanied with a certain amount of pain. A saline purgative was given, to prepare the system for the reception of quinine, of which latter drug one gramme (15½ grains) was ordered to be taken during the next two days, with the daily use of a decoction of taraxacum. The fever remained the same. Fearing lest there should be a disturbance of the regular course of menstruation, of which the

epoch was at hand, and believing that the flow would diminish or suppress the hepatico-splenic engorgement, Dr. Casanova resolved to delay applying leeches to the anus, as he had first intended to do, and gave small doses of quinine with sulphite of soda. Menstruation was, however, normal, and had no effect on the spleen and liver. The powders caused frequent nausea and alvine dejections, without at all changing the febrile state of the patient. Eight leeches were directed to be applied to the anus, which caused a free flow of blood, with the effect of removing the hepatico-splenic complication. A gramme and a half (23 grains) of quinine was divided into sixteen pills, with extract of cinchona, to be taken in four days. On the third day, after the patient had taken eight pills, the catamenia re-appeared in normal quantity. The pills were continued. On the fourth day Dr. Casanova was suddenly summoned for an alarming menorrhagia, the woman having lost more in a few hours than she usually did during the whole period. The pulse was thready, and she had vertigo and was faint. Ice externally, and ergot and rhatany internally, were ordered; but it was found the next day that the loss of blood had ceased almost instantaneously without the use of any of these remedies. The four remaining pills were ordered to be taken, and seven and a half grains of quinine, divided into eight pills, to be taken in two days. The fever entirely left her, and the patient quite recovered.

Two principal considerations arise out of the preceding case.

1. The disulphate of quinine has neither any hæmostatic properties nor any stimulating effect upon the uterus, because the metrorrhagia showed itself after the patient had taken nearly seventeen grains. 2. If in the present case the patient had not been treated for ague, but on the contrary, had been treated by quinine for the first time, immediately after the metrorrhagia, this remedy would have had all the honours of the cure, and it would not have been thought to be spontaneous and natural.

Being sceptical of Monteverdi's theory of the action of quinine as a hæmostatic and uterine excitant, Dr. Casanova has carefully noted any cases bearing upon the subject; the following is a second instance tending to prove the fallacy of the theory.

Madame G. S., aged fifty, delicate, commenced to menstruate late, the discharge being at first scanty. Afterwards the catamenia became regular and abundant. In March (the author is writing in November), they became profuse, and lasted twenty days, followed by a continuous and excessive leucorrhœa, alternating with a bloody discharge that only ceased with the menstrual flow, which was very profuse. This condition continued without improvement until July, when Dr. Casanova was called in. Fifteen and a half grains of quinine were given in a dozen pills with extract of taraxacum. The pains and hæmorrhage diminished the same night, after taking only four pills; the other six pills on the next day entirely removed every ache, and stopped the hæmorrhage, and the patient was completely restored to health. No other remedy, not even a change in the patient's habits and mode of life, could be considered as contributing to the cure, which was permanent. Here the cure must be regarded as exclusively due to the quinine; the promptitude of its action and its efficacy being perfectly marvellous to the patient herself.

W. C. GRIGG, M.D.

NETTER ON THE APPLICATION OF THE PRACTICE OF OVARIOTOMISTS TO PUERPERAL PERITONITIS.—Dr. Netter (*Revue Médicale de l'Est*, Feb. 15, 1875), says that this problem must be solved by three considerations, moral, scientific, and therapeutic.

Moral Considerations.—Has a medical man the right, in a case of puerperal peritonitis, to practice incision, an operation without precedent and condemned by tradition—the latter, however, being confronted by the facts in cases of ovariectomy? Is it not the duty of every medical man to fight against disease even unto the death-struggle? He supposes two neighbouring wards of a hospital, one filled with cases for ovariectomy, and the other with puerperal peritonitis, and contrasts the mortality in the one and the other, and also the treatment; the treatment adopted saving many grave cases after ovariectomy, as recorded by Spencer Wells, Sims, etc., and the ordinary method of treatment saving few cases of puerperal peritonitis.

If the first case in which we try the injections be fatal, are we to reproach ourselves? Rather let us consider how we must reproach ourselves for all those whom we have allowed to die if this becomes, as he believes it will, the recognised treatment.

Scientific Considerations.—Ovariectomists work by constantappings and injections, placing drainage-tubes in Douglas's space, etc., and obtain marvellous and rapid results from thus getting rid of the peritoneal effusion. The theory on which these plans of treatment are based is, that the absorption of these fluids causes septicæmia. Dr. Netter does not believe in septicæmia, but considers that the effusion acts as a local irritant poison; and he supports his opinion by quoting from Sims, how the fluid stings the fingers of the operator, and how immediate is the amelioration in the fever, etc., when injection is practiced. He points out that the fluid is often *post mortem*, the only indication of the cause of death, and that the ordinary signs of peritonitis are absent. The fluids act as local irritants, not by absorption; witness the gastric, nervous, and reflex phenomena with the pyrexia. His conclusions are the following.

1. The septicæmia of ovariectomists as a cause of death is a delusion.

2. Their practice founded on this false theory might be simplified.

3. The injection of an abundant quantity of warm water to dilute and render harmless the poison is alone required.

He states that Nussbaum has found that the injections during the first few hours are those which do good; after this the fluid effused is diluted and less irritating.

Applying what has been said to the case in point, puerperal fever, he quotes Velpeau on the irritating and acrid nature of the lochia and other fluids; and Cruveilhier to show that absorption is usually through the lymphatics, and rarely through the veins direct into the blood, and giving rise to deposits in the lungs and liver; when through the lymphatics, the dangerous materials are stopped in the glands. Hence we have not to contend with a constant supply of poison, but only with the immediate effects of the first effusion into the peritoneum.

Therapeutic Considerations.—When trying new remedies we should feel or grope our way along. The indication is to get the water into the peritoneal cavity. This may be done by direct incision or by

two indirect methods, by absorption or by injection into the veins. The first he would attain by injecting the water into the uterus in such a way that, while it washed out the discharges, a constant supply was held in the fundus. He does not see why injection into the veins should not be tried here as well as in cholera. Whichever of these plans is tried, percussion of the abdomen is to be practised, to find when the desired result is obtained.

With regard to direct injection, he does not think the adhesions are as solid during life as they are twenty-four hours later, when the *post mortem* examination is made; and in many cases they are absent.

He would have each of these methods tried during an epidemic, with the double view of curing the patients and throwing light on the nature of the malady.

Experience must teach us how to proceed in various cases, and how to supplement the injection, where necessary, by draining, more extended incisions, etc. Surgical intervention should be practised at the moment of invasion, so as to prevent adhesions from forming.

J. KNOWSLEY THORNTON.

TOXICOLOGY.

WILL AND CHARTERIS ON CHLORAL AS AN ANTIDOTE TO STRYCHNIA.—The *British Medical Journal* for January 23 contained a report by Dr. Hughes Bennett, on behalf of the committee appointed by the British Medical Association to investigate the antagonism of medicines, in which it was shown that in the lower animals chloral acts as an antidote to poisonous doses of strychnia. Dr. Ogilvie Will, of Aberdeen, records, in the *Edinburgh Medical Journal* for April, an opportunity which he lately had of demonstrating that this fact is true also of the human subject.

A druggist's apprentice, aged eighteen, swallowed, with suicidal intent, a quantity of pure strychnia. The lad thought he had taken five or six grains—'certainly not less than four'—but the exact amount could not be ascertained as he had emptied it out of a bottle at haphazard; but from the rapidity with which the symptoms appeared—only a few minutes after swallowing the poison—and, from their severity, it was evident that the dose must have been a large one.

Medical assistance was quickly obtained; and when Dr. Will saw the patient, an emetic had been given and other attempts made to induce vomiting, but without success; violent attacks of convulsions had already commenced, recurring at intervals of about five minutes; often several fits would occur in succession with only a minute or two between each. Dr. Will at once sent for some chloral; but whilst this was being procured the fits rapidly increased in severity and in duration, and when it arrived the patient appeared actually moribund—as if he could not live many minutes. Thirty grains of chloral

were at once administered by the mouth, and 'in a very few minutes the good effects began to manifest themselves—the intervals between the spasms became longer and the spasms themselves lessened in severity.' Another thirty grains were then injected under the skin, and almost immediately afterwards a further change for the better was observed. Later in the afternoon, however—the poison having been taken a little before 2 P.M.—the fits again began to increase gradually in frequency and intensity; accordingly at 5 P.M. thirty grains of chloral were again given by the mouth, and at 6.30 fifteen grains were injected hypodermically. After this the fits subsided; occasional twitchings continued for a few hours; these ceased during the night, and next day the patient was convalescent.

Dr. Charteris, of Glasgow, reports a very similar case in the *Lancet* for April 10. In this instance the patient, a very strong, healthy man, aged thirty-nine, deliberately swallowed the contents of two sixpenny packets of 'Gibson's Vermin-Killer' mixed with whisky and ginger-beer, each packet containing fully two grains of strychnia. The poison was taken at about 11.30 A.M., soon after a very substantial meal of ham and eggs, etc., and the symptoms came on very slowly and gradually. It was not till 3.30 P.M. that he was brought to the Royal Infirmary; violent attacks of convulsions were then occurring about every ten minutes. The stomach-pump was used but the fits continued to increase in severity and frequency until 4.50, when ten grains of chloral were given, and the dose was cautiously repeated at intervals of about twenty minutes. There was little change until forty grains had been given, but then the improvement was rapid and marked; the spasms subsided into mere muscular twitches, and the patient became calmer. The chloral was now given at gradually longer intervals; about 3 A.M. the spasms ceased altogether, and the patient complained only of aching and soreness in the muscles. He recovered completely in three or four days.

J. W. LANGMORE, M.D.

REVIEW.

Manual of Public Health for Ireland. By DRS. T. W. GRIMSHAW and J. W. MOORE, PROFESSOR J. E. REYNOLDS and R. O'B. FURLONG, Esq., Barrister-at-Law. Dublin: Fannin & Co. London: Longmans, Green & Co. 1875.

This compact little manual has been compiled to meet the wants of the officers of health for Ireland, and explains the duties imposed upon them by the Act of 1874, in preparing the enactments of which use was made of the valuable system of dispensary service peculiar to Ireland. The machinery provided by the existence of this system ought to render the Act comparatively easy of application, the dispensary medical officers being appointed health officers for their own districts, subject, of course, to the superintendence of specially appointed inspectors of approved competence. The present work is the joint labour of Drs. Grimshaw and J. W. Moore, both diplomates in state medicine of the University of Dublin, whilst the chemical part has been intrusted to Professor Reynolds and the legal part to Mr. R. O'B. Furlong, barrister-at-law. It is a difficult matter to compress the wide range of subjects required for officers of health into the space

of little over 300 pages of a duodecimo volume, but the task has been, on the whole, well accomplished, although there is still undoubted room for improvement. The earlier chapters are devoted to an analysis of the various acts, under which the sanitary officers are to work, and contain a summary of their provisions and a good index to the leading points in the appendix. Also there is a list of the chief towns and boroughs, and the sanitary districts of Ireland. Following on these is a section on statistics, which contains much useful information. Then come chapters on preventable diseases, treating in the first place of zymotics, among which we are glad to perceive that the authors reject the so-called simple (or common) continued fever as a special fever apart from true typhus, enteric, or relapsing. They give a short but instructive table, showing that it nearly always prevails in conjunction with one of the other forms; thus, from the records of the Cork Street Hospital, of forty-two houses furnishing more than five cases of fevers each:

13	houses	furnished	cases	of	three	kinds	of	fever.
19	"	"	"	"	simple	fever	and	typhus.
4	"	"	"	"	simple	fever	and	enteric.
4	"	"	"	"	typhus	and	enteric.	
2	"	"	"	"	simple	fever	only.	
0	"	"	"	"	typhus	only.		
0	"	"	"	"	enteric	only.		

19 houses furnishing typhus furnished also simple fever.

It is to be hoped that in time this vague disease will disappear from our returns as diagnosis becomes more accurate. We gather, however, that the authors believe that typhus may be generated *de novo* from simple overcrowding, a thesis which is, to say the least, doubtful, although it must be admitted that after the direct communication of the poison, crowding is the most powerful factor in its propagation. There is certainly one peculiarity about typhus, which has been noticed by many observers, and lately brought out very strongly by Guillemin, namely, that a certain amount of the poison is necessary for its manifestation, hence the importance of crowding as a factor; in some other diseases usually accepted as communicable, an apparently minute quantity of poison is sufficient; in short, quantity rather than quality appears to govern the propagation of typhus. Under the head of erysipelatous affections the authors refer to the vexed questions of hospitalism, and point out from the recent experience of the Rotunda Hospital at Dublin, that extreme and scrupulous care in sanitary measures has practically reduced puerperal fever to a minimum, and quite abolished *trismus nascentium*. This bears out the view held by some competent observers that where sanitary precautions are rigidly carried out there is no reason why large buildings should not be quite as healthy as small ones. Some instructive statistics are given with regard to the influence of vaccination from the experience of the Irish hospitals. In the chapters on diseases arising from food, constitutional diseases, and the diseases of artisans, there are some interesting remarks; but in the last, lead, arsenic and mercury are said to be the only mineral poisons likely to affect the artisan; but surely both phosphorus and potassium bichromate are sufficiently poisonous and affect a considerable number, and the list might be extended. In the chapter on diseases arising from vicious habits there are some very sensible remarks, and we cordially endorse the statement that 'comfortable dwellings will do more

to promote sobriety than any amount of legislation or teetotal agitation.' No reference is made to the growing use of narcotics, but perhaps the habit may not be so constant in Ireland as it is in England, where opium especially is very largely used among the lower classes, particularly in the low lying and swampy districts; perhaps the non-malarious character of the Irish peat-bogs (referred to at p. 174) may account for this, supposing our surmise to be correct. The authors support the Contagious Diseases Acts, and call for their application to the civil population. Food and its adulterations are treated of, as well as the questions of ventilation, examination of air, water analysis and supply, and sewage disposal; these are followed by chapters on contagion and disinfection, and hospital construction. It is always a difficult matter to lay down rules for chemical examination when space is limited, and the scientific knowledge and experience of those for whom the instruction is intended are limited also; there is a risk on the one hand of going beyond the capabilities and opportunities of the reader, and on the other of being too brief and bald, and not sufficiently explicit. The present work gives processes which are in several cases too complicated for an ordinary health officer whose time is much occupied, and whose appliances are few, whilst it does not go far enough to be of real value to a professional analyst. This, however, is a matter of less importance comparatively, as so many good works exist in this branch of knowledge. The closing chapters treat of meteorology, and the influence of climate and season in disease, in which is brought together a good deal of useful and interesting information, and the appendix contains a convenient list of apparatus and chemicals, as well as the tables most generally required for the reading of meteorological instruments and keeping weather records.

MISCELLANY.

M. WURTZ has given in his resignation as Dean of the Faculty of Medicine in Paris; his successor is not yet appointed.

THE names of the fifteen candidates for the Fellowship selected by the Council of the Royal Society to be recommended for election at the meeting on June 3 are W. Archer, J. R. Bennett, D. Brandis, J. Caird, J. Casey, A. Dupré, J. Geikie, J. W. L. Glaisher, J. B. N. Hennessey, E. Klein, E. Ray Lankester, Captain Nares, R. S. Newall, W. C. Roberts, and Major-General Scott.

DISEASE IN THE COFFEE-PLANT.—A disease in the coffee-plant at Ceylon has lately been discovered which threatens scarcity of this product unless speedily checked. It is called 'leaf-disease,' and, as its name implies, is principally apparent in the death of foliage, though the produce of the berries is also considerably reduced. It is believed by competent authorities to be mainly caused by exhaustion. The Government of Ceylon have taken up the subject with a view to its thorough investigation.

THE Royal Society during the present session have elected the following nine foreign members:—Pierre J. van Beneden, of Louvain; Joseph Louis François Bertrand, of Paris; Alfred Louis Olivier Des Cloizeaux, of Paris; Hippolyte Louis Fizeau, of Paris; Elias Magnus Fries, of Upsal; Jules Janssen, of Paris; Auguste Kekulé, of Bonn; Gustav Robert Kirchhoff, of Berlin; and C. Ludwig, of Leipsic. The Earl of Carnarvon, Mr. W. E. Forster, and Sir Stafford Northcote have also been elected Fellows of the Society.

THE CAUSE OF THE LATE AERONAUTIC FATALITY.—At the last meeting of the Paris Academy of Sciences, M. Cohn stated that the cause of the deaths of MM. Croce-Spinelli and Sivel was unquestionably owing to the sudden diminution of atmospheric pressure. It is also to be noted that the two aeronauts who died had taken food before the ascent, whilst M. Tissandier was fasting. MM. Croce-Spinelli and Sivel, under the influence of this sudden diminution of atmospheric pressure, underwent what occurs in animals attacked by gaseous indigestion; that is to say, that the production of the gas, by driving back and distending the diaphragm, paralyses the action of that muscle, whence asphyxia results. M. Cohn thence infers that the best advice to give to aeronauts is to take no food before the ascent, or to take alcoholic liquors in place of solid food, as they do not give rise to gaseous fermentation, and are favourable to calorification, whilst they furnish a means of resistance to lowerings of the temperature of the upper regions of the atmosphere. M. Cohn differs from M. Paul Bert, who believes that it was the want of oxygen which caused the death of the aeronauts, and ascribes it solely to the sudden diminution of atmospheric pressure.

THE COLORADO BEETLE.—Dr. Kalender, of Linderhöhe, near Cologne, gives a long account, in the *Kölnische Zeitung*, of the new enemy to the potato which has caused much ravage in the potato plantations of the United States, namely, the Colorado beetle (*Doryphora decemlineata*). Dr. Kalender applied to the Prussian Minister for Agriculture, and obtained the most reliable information, which is based upon a report of Mr. C. Riley, in the annual report on the noxious, beneficial, and other insects in the State of Missouri. It appears that the insect passes the winter in the ground, but, as soon as the potato-plants have developed their first shoots, the beetle shows itself. The females then deposit their orange-coloured ova, in lumps of ten to twelve, upon the under surfaces of the leaves; the larvæ appear after five to eight days, and begin their destructive work, which lasts two or three weeks, after which period they transform into nymphæ; ten to fourteen days later the young beetles appear; thus one summer can see three or four generations, of which the last one passes the winter in the ground. The insect does not confine its devastations to the potato, but has also been found to attack the young shoots and leaves of *Cirsium lanceolatum*, *Anaranthus retroflexus*, *Sisymbrium officinale*, *Polygonum hydropiper*, *Solanum nigrum*, *Chenopodium hybridum* and *album*, and even of *Hyoscyamus niger*. This variety of plants shows that the insect has great powers of adapting itself to its food, and to this must be ascribed the fact that it can only with the greatest difficulty be got rid of. The home of the insect was in the Rocky Mountains; with the westward progress of agriculture the cultivation of the potato approached the birth-place of the insect, and it transferred its dwelling to the potato fields, which of course were welcome food; thus in a short time it became a general plague. In 1859 it began its eastward progress, and has now reached the coast of the Atlantic; whether it will cross this ocean and begin its devastations in Ireland remains to be seen; much may, however, be done to prevent its appearance in Europe. The means used for its destruction are various; the most successful one has been the so-called Schweinfurt green (arseno-acetate of copper). This is mixed with flour and water, and the plants are sprinkled with the mixture. Although highly poisonous to animal life, the Schweinfurt green does not poison the soil, as it is perfectly insoluble in water, and the destruction of the noxious insect is almost complete.

ABSINTHE.—In the Cantor Lectures lately delivered by Dr. Richardson at the Society of Arts, he remarked that, as this drink is now sold in this country, and the consumption is on the increase, a clear description of the evils resulting from its use may be disseminated with advantage. He states that absinthe is peculiarly formidable. In this liquor five drachms of the essence of absinthum,

or wormwood, are added to 100 quarts of alcohol. Thus the liquor is not only very strong as a mere alcoholic drink, but it is charged with another agent which has been discovered to exert the most powerful and dangerous action upon the nervous functions. The essence of absinthum in doses of from thirty to fifty grains produces, in dogs and rabbits, signs of extreme terror and trembling, followed by stupor and insensibility. In larger doses it causes epileptiform convulsions, foaming at the mouth, and stertor of the breathing. Its effects, as they occur from the taking of it in the form of absinthe in man, have been most ably described to Dr. Richardson by one who indulged in it until it induced in him the peculiar epileptiform seizure. He described the effects as resembling those produced by hashish, the narcotic of the East, which has been known for so many ages as the nepenthes of Homer, and which owes its properties to extract of Indian hemp or *Cannabis Indica*. The partial insensibility caused by the absinthe is attended with the ideal existence of long intervals of time, in which the events of a whole life are arrayed and appreciated, to be succeeded by terrific hallucinations and intellectual weakness, ending in unconscious struggling as if for life. In time, if the use of the absinthe be continued, these phenomena become permanently established, and the result is inevitably fatal. The doubly poisonous absinthe is made the more seductive to its victims by the fact that it excites a morbid craving for food which is never felt except when it is tempted by the destroying agent. Indeed, such are the terrible consequences incident to this agent, that Dr. Richardson agrees with Dr. Decaisne in maintaining that it ought, by legal provision, to be forbidden as an article for human consumption in all civilised communities. Even in small quantities taken daily, say one or two wine-glassfuls, it causes quickly a permanent dyspepsia, and, what is of still more consequence, it tempts its victims on and on, so that they cannot take food until absinthe has prompted the desire for it, by which time they are too often hopelessly and mortally in its power.

IT is a well-known fact that the most eminent members of the medical profession have unequivocally pronounced against the use of gas, as injurious to both health and sight. It is therefore recommended that for purposes of daylight Chappuis' Patent Reflectors should be adopted. Particulars of the invention may be obtained at 69 Fleet Street, London.—[ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.: free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MAY 5, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CLINICAL REMARKS ON DIPHTHERIA. BY DR. HENOCH, CLINICAL PROFESSOR IN THE CHARITÉ HOSPITAL, BERLIN.*

The subject of diphtheria has already on repeated occasions been discussed in this society; and if, notwithstanding this, I again invite your attention to the consideration of some points relating to this disease, I believe that I am justified in doing so, on the one hand by the interest which we all have in this formidable malady, which has become endemic among us, and on the other hand, by the circumstance that it is still spreading more and more widely as an epidemic, and threatens to assume a rather destructive character in our city. I will not trouble you with a prolix introduction, but will confine myself to laying before you some points for discussion.

First, as to the anatomy of the disease; you all know that the diphtheritic exudation, or better, the diphtheritic process, is anatomically distinguished from the croupous, by the peculiarity, that in diphtheria the mucous membrane is infiltrated with the morbid elements, while in croup the deposit lies free on the membrane. We have, however, known for some time that in diphtheria both these forms are observed in one and the same individual; the infiltration, which we specially call diphtheritic, showing itself in the pharynx and as far down as below the epiglottis, and sometimes on the vocal cords; while further down, as far as the bronchial tubes, a loosely lying so-called croupous deposit appears. I will not here enter on the question of the cause of the difference—whether it depends on structural conditions of the various portions of mucous membrane, or on other conditions; I will only remark, that the difference does not absolutely hold good. In the writings of earlier competent authorities, *e.g.* in the great work of Rilliet and Barthez, you find it stated that the so-called ‘croupous’ membrane does not always lie quite loose; but that (as we may frequently convince ourselves by examination) it may be firmly connected by fine adhesions to the mucous membrane, and that it is not always easy simply to remove it as a tube. It is, indeed, expressly stated in one part of the work above referred to, that, especially in cases where there are only limited patches of exudation in the larynx and trachea, these are sometimes so firmly attached that, in the attempt to remove them by the forceps, a portion of the mucous membrane is at the same time torn away. I have had the opportunity of observing two cases of this kind in the Charité Hospital.

A girl, three years old, was admitted with diph-

theria and croup; she coughed up several tubes corresponding with the calibre of the trachea; and at last tracheotomy became necessary. During the operation no membrane was discharged, but only a bloody yellow mucus; she died the next day. At the *post mortem* examination, made by Herr Orth on January 15, 1874, there were found very abundant free croupous deposits, extending nearly to the bifurcation of the trachea; but a few centimètres above the bifurcation there commenced a very distinct yellow-grey infiltration of the tracheal mucous membrane, extending to the mucous membrane of the right bronchus and a little beyond. It was only by scratching with the scalpel that this mass could be removed from the air-tubes; and, in doing this, an evident loss of substance was left behind.

The second case occurred on January 25, 1875, in a boy with terminal diphtheria. Besides the well-known appearances in the pharynx, the whole mucous membrane of the trachea was infiltrated and of a yellowish white colour; a free deposit of croup-membrane was not to be perceived. Proof was in this case afforded that diphtheritic infiltration of the mucous membrane may take place below the vocal cords, an event which rarely occurs. I have put together twenty-one necropsies of cases of diphtheria made in my clinic; in sixteen of these there were only free croupous deposits below the vocal cords or lower down (the membrane extending deeply into the bronchial tubes in eight); while in only two cases were there free deposits and diphtheritic infiltration, or the latter alone. In two other cases there was only simple laryngo-tracheitis, with diphtheria of the pharynx; and in one no disease could be detected below the epiglottis.

It being proved that diphtheritic infiltration may take place below the vocal cords, it might be thought that the so-called croupous exudation might be met with in the pharynx also. In fact, it not rarely happens that the mass is not only infiltrated, but partly lies loose; and we met with such a case in a necropsy a few weeks ago. It was that of a boy whose malady began with a pseudo-croupal affection. I examined the pharynx, and found absolutely nothing more than an ordinary angina. At the end of two days complete croup was developed; tracheotomy was performed; but he died while it was being done. At the *post mortem* examination there was found a very distinct membranous deposit in the larynx, especially about the vocal cords and farther upwards, along with œdema of the ary-epiglottic ligaments. The tonsils were not much enlarged; but on section they presented in parts a yellowish-white infiltration, and were covered with a perfectly free and easily removable croupal membrane. My colleague, who made the necropsy, believed it to be a case of croup and not of diphtheria, an opinion which I cannot share. I believe that the imperishable services which pathological anatomy has rendered to medicine would be still greater, if anatomists had not too great a disposition to emancipate themselves from clinical observations. They would then be less likely to come into collision with self-imposed barriers. From a clinical point of view, the case to which I have just referred was, in my opinion, distinctly one of diphtheria. When I consider, that at the time diphtheria was of almost daily occurrence in my wards, arising from infection in the institution itself, and when in these circumstances I observe a case which clinically runs its course quite like all

* Read before the Berlin Medical Society, February 17, 1875. (*Berliner Klinische Wochenschrift*, April 26.)

other cases, the pharynx, however, showing a croupous exudation instead of the infiltrated mucous membrane generally met with, this anatomical variation does not seem to be one sufficient to remove the case from being one of numerous cases of diphtheria observed at the same time.

We will take this opportunity of making some remarks on the relation of croup to diphtheria. You are aware that croup, *i.e.*, the development of the peculiar croupous membrane in the larynx, was formerly described by many as an idiopathic disease. In the discussions which took place in this society some years ago, a diversity of opinion prevailed; our older members, whose experience extends a long time back, regarded the existence of a *primary* croup as fully established, while the younger portion of the society appeared to oppose this view, and to be desirous of regarding croup as of a diphtheritic character in all circumstances. This is connected with the fact, that the experience of the former extends to a time when diphtheria was met with very rarely or not at all. As far as my opinion goes, I must say that I fully recognise the existence of croup as a distinct disease. To this I will add, that mistakes may rather easily occur; and I would especially direct your attention to one which may arise from the fact, that the diphtheritic affection of the pharynx may have its seat in places where nothing is to be seen during life, while the most that we can make out is an angina, and where laryngeal croup suddenly sets in. Thus, for instance, cases occur in which only the posterior surface of the velum is affected with diphtheria, the anterior remaining quite free; or where the lowest part of the pharynx, close above the œsophagus, is attacked. Two such cases came under my notice in April, 1874. One was that of a little girl, a year old, who lay in my ward with whooping-cough, and consequent pneumonia. She was suddenly seized with symptoms of croup. The pharynx was carefully examined; we found the tonsils free, but were not quite sure whether there were whitish deposits behind in the pharynx. Tracheotomy was performed; and after death it was found that quite at the lowest part of the pharynx, where it passed into the œsophagus, there was a diphtheritic infiltration; besides this, the posterior surface of the velum was strongly infiltrated, while nothing was to be seen anteriorly. Another case was that of a boy, four years old, who also died after tracheotomy. The necropsy showed redness of the tonsils and of the pharynx; the tonsils were swollen. Quite at the lowest part of the pharynx, below the base of the tongue, near the epiglottis, there was a very distinct diphtheritic infiltration; and the process had extended from this part as far down as the middle-sized bronchi. There were also glandular swellings, parenchymatous nephritis, and swelling of Peyer's patches. A third case came under my notice in January, 1875. A tuberculous boy was attacked with aphonia, to which symptoms of dyspnoea were soon added. At the *post mortem* examination, diphtheritic infiltration was found below the base of the tongue around the epiglottis, but no where else; but at the same time there were all the signs of laryngeal croup. The last case occurred to me yesterday (February 16), in a child who was the subject of general tuberculosis and extensive peritonitis; and at last was attacked with diphtheria. The velum was free; the tonsils were only superficially ulcerated; the diphtheria was only developed quite at the lowest part of the pharynx; and further down in the larynx there was croup.

If such cases come under treatment, and nothing be seen on examination of the pharynx, and then croup suddenly set in, it is easy to regard the case as one of simple primary croup, since the preceding diphtheria in the pharynx has been overlooked. If any accuse us of neglect in not detecting the pharyngeal affection by the laryngoscope, I reply that, if this instrument could always be used, such a mistake would not easily occur. You all, however, know that it is only with difficulty that the laryngoscope can be successfully used in the case of children. Instances certainly occur, and we just now have one of the kind, where an inspection of the larynx of a boy five years old was quite successfully made, but not until the most important symptoms had passed off. In most cases, however, where the child is in a state of orthopnoea, grinds its teeth, and has a constant dribbling of saliva, you will not be able to use the laryngoscope at all, or at most very imperfectly; and I must consider the information deceptive which is believed to have been derived from its use.

Mistakes of the kind which I have described are especially liable to occur in children's hospitals; for it is one of the most frequent of occurrences that diphtheria suddenly attacks children who are convalescent or who are still suffering from other affections. How can we always recognise the diphtheria? The primary disease is so marked that the first indications of diphtheria are mostly overlooked, until symptoms of croup quite suddenly appear; this I have observed twice in children who on the previous day had been playing in the play-rooms. It would be necessary to make a daily examination of the pharynx of every child in the hospital—a measure which is far more easily recommended than carried out.

I am distinctly of opinion that there is a primary fibrinous croup, which has nothing in common with the infective disease designated diphtheria. Doubts to the contrary will indeed always be expressed on this point by sceptics, who say, 'we do not believe in such a croup, not even when absolutely no disease, is found in the pharynx on *post mortem* examination.' They usually support themselves with the assertion that it is not necessary that the diphtheria should always attack the pharynx, but that it may appear primarily in the larynx, the pharynx remaining quite free. I will not here examine whether there are or not any grounds for this opinion, because I believe that it is not correct. In proof of this existence of a primary croup, it is to be especially remembered that we have to find a disease which notoriously has a disposition to always produce a catarrh of the larynx and trachea. If under these circumstances, without any affection of the pharynx, croup is developed from a simple laryngeal catarrh, we may well maintain that it is only an aggravation of the catarrh, a 'plastic croup,' as was formerly said. Measles is a disease of this kind. We know that from the first it is always accompanied with catarrh of the larynx and trachea. If at an early period in the eruptive stage of measles this catarrh assume the croupous character, the pharynx remaining free, no one can well deny that it is a primary inflammatory croup, proceeding from a simple catarrh. I observed a case of this kind in a boy three years old, who was admitted in May 29, 1873, into the Charité, with measles in the stage of efflorescence. The eruption had just appeared on the face; the temperature in the evening was 104.9°, in the morning, 103°; and the characteristic laryngeal catarrh was so severe,

that I was obliged to consider whether there was real laryngitis. The cough was harsh and aphonic, the voice hoarse. By the most careful examination nothing further could be found than a simple angina, or rather the development of the exanthem in the mucous membrane of the throat and palate. Having learned from experience that this catarrh might very readily become aggravated, I adopted an active antiphlogistic treatment; applied leeches, gave tartarised antimony, and had the satisfaction of seeing all the symptoms remarkably relieved. On the 30th, the pulse had fallen from 150 to 116, the temperature to 101° , and the respiration from 44 to 32. The hoarseness, however, remained; when he coughed, some laryngeal sound could still be distinctly heard. In this way, four days passed without fever, while the laryngeal symptoms continued. Suddenly, on the evening of the fourth day (June 3) the temperature rose to $101^{\circ}3'$, and the next morning to $103^{\circ}1'$. From twelve o'clock at night there was complete croup, so that at midday, during the clinical visit, tracheotomy had to be performed. Through the opening in the trachea we were able to draw out a long cylinder, which extended as far as the bifurcation; and some shreds of membrane were afterwards coughed up. I believe that such cases prove beyond doubt that a complete croup may be developed from a catarrh; but I will add, that in our time genuine primary croup is in a considerable minority in comparison with the infectious diphtheritic malady.

Another remark that I have to make is on a sequela of diphtheria, namely, paralysis; and it is entirely of a therapeutic nature. It is known that recovery from diphtheritic paralysis frequently takes place spontaneously if we have the patience to wait for it; and further, that electricity is often used with advantage. The following cases are well calculated to prove that we may bring about a more rapid recovery if we do not leave it to Nature, but treat the malady with injections of strychnia. Both cases were observed by me in the polyclinic of the Charité.

Hedwig R., a girl eleven years old, came under notice on April 7, 1874, having suffered from diphtheria six weeks previously. For three weeks, there had been paralysis of the palate; the uvula and velum were perfectly motionless both in phonation and in inspiration; the voice was nasal; drink flowed from the nose; there was paralysis of accommodation of the eyes (she could not read, and had double vision at a distance); there was paralysis of the muscles of the back of the neck, so that the head was bent forward and could not be lifted backward. Besides these symptoms, there was also the remarkable phenomenon which I cannot explain, namely, that when the girl was directed to close her eyes, both eyelids were seized with a twitching vibratory movement, which ceased as soon as the eyes were opened. In other respects, nothing abnormal was to be observed. The patient had already taken quinine and iron without benefit. On April 7, I gave the first injection of two milligrammes (about $\frac{1}{30}$ th grain) of strychnia, and ordered the quinine and iron to be continued. On the 9th, a second injection was made; and on the 11th, she could hold up her head considerably better; a third injection was made. On the 13th, speech was essentially impaired; the movements of the velum were more distinctly visible, but reading was still impossible; a fourth injection was given. From the 17th, she could read; and on May 1 she was discharged com-

pletely cured. In all, one-fifth of a grain of strychnia was used. It is to be remarked, that the vibratory twitchings of the eyelids still continued after every other symptom had been removed, so that I am disposed to regard it as something purely accidental.

The second case was that of a boy, aged ten, who was admitted December 4, 1874. At the beginning of October he had an attack of diphtheria, by which he was confined to bed for a fortnight. He then returned to school; and immediately afterwards paralysis set in. Here, also, there were paralysis of the velum, discharge of fluids through the nose, nasal unintelligible speech, together with paralysis of the muscles of the nape, impossibility to read, and paresis of the lower limbs. The boy tottered in walking, especially in turning round, and showed distinct ataxic symptoms. On the 4th, I injected $\frac{1}{45}$ th of a grain of strychnia; and subsequently gave three other injections of $\frac{1}{30}$ th of a grain. On the 14th, walking and speech were already considerably improved. Under a continuance of the injections, the symptoms rapidly diminished, and after ten injections (about $\frac{1}{3}$ of a grain of strychnia in all being used) recovery was complete.

In both children, the injections were made in the nape of the neck. On no occasion was there any untoward symptoms. If it be objected that the cure was not produced by the strychnia, but rather was spontaneous, I would remark that no one who observed the rapidity with which the recovery took place could doubt the therapeutic action of the injections. I had at first some hesitation in trying these injections on children; but the experience of Demme, the director of the Children's Hospital at Berne, who praises strychnia as a remedy in infantile paralysis, put me at ease. Since then I have used strychnine injections in children in a rather large number of cases, not only for paralysis, but for prolapsus ani; and my experience agrees with that of Demme, that, if proper care be taken, there is no fear of mischievous results at this age. But that not only a non-injurious but a distinctly good action may follow is proved by my cases, supported as they are by the observations of Dr. Acker of Erlangen (see the *Deutsche Archiv für Klinische Medicin* of last year) which, however, were indeed not made on children but on grown persons.

A. HENRY, M.D.

VULPIAN'S EXPERIMENTAL PATHOLOGICAL STUDIES ON THE PHYSIOLOGICAL ACTION OF TOXIC AND MEDICINAL SUBSTANCES.

M. Vulpian is now delivering a course of lectures at the Paris Faculté de Médecine on the above subjects. In the first lecture, reported in *Le Progrès Médical*, April 3, he investigates the meaning of the expression physiological action of poisons and drugs, points out the importance of this knowledge from the therapeutical and physiological point of view, and indicates the method to be adopted in the investigation of this physiological action. He continues by observing that it is scarcely necessary to define what should be understood by the words drugs and poisons. Drugs are substances which are administered either with the object of restoring functions disturbed by disease to the normal condition, or of curing lesions which may have attacked the various tissues and organs. Poisons are chemical substances which, when introduced into the animal

organism, may produce lesions or serious functional disorders threatening life. M. Vulpian here defines the difference between viruses and venoms. Viruses, according to him, are albuminoid substances, originating in organic matter, either during life, or as a consequence of the decomposition of matter (cadaveric virus), and which, when they enter the circulation of a living person, also bring on serious morbid troubles; generally mortal in some cases, in others invariably so, as in the case of the virus of rabies.

Viruses differ from poisons, not only in their constitution, but also in other very important characteristics. Thus, whilst the action of poisons is, in a general way, of an intensity in proportion to the dose absorbed, there does not appear to be a very exact relation between the quantity of the virus introduced into the circulation, and the violence of the effects produced by these substances. On the other hand, viruses do not, like poisons, produce an immediate effect; they only act after a certain period of time, called a period of incubation. Venoms resemble poisons much more closely than viruses. They differ from poisons principally in their production; being, in fact, products of glandular secretion. Chemical substances, comparable to those of poisons, have not been extracted from them; but like the latter, they produce immediate effects proportional to the amount of the substance absorbed. Certain venoms cause absolutely similar effects to those produced by certain poisons. Thus the venom of the frog acts on the heart like digitalis; the venom of the triton, or water-salamander, also has the same action. A large number of toxic agents are employed as drugs; that is to say, either applied externally, or administered internally to produce a remedial effect.

There is no defined boundary between a medicine and a poison; a medicine may become a poison if taken in large doses, and reciprocally, a poison may act as a medicine if given in small doses. Phosphorus, arsenic, mercury, opium, belladonna, sulphate of quinine, may be instanced as substances which will act either as medicines or as poisons, according to the dose taken.

M. Vulpian then proceeds to state his intention of studying the effects of a certain number of toxic and medicinal substances, taking them as types and determining their physiological action. The physiological action of a poison or a drug will be distinguished from the effects produced by it, these effects being lesions or functional troubles produced by the influence of these substances on the organism. He takes the physiological action of toxic substances and drugs as the physiological mechanism by which the effects are produced, and goes on to show by some examples the difference which should be established between the effects of a toxic substance and its physiological action. He instances three frogs as examples. In one a certain quantity of strychnine is injected under the skin of the hind leg; in the same way another is made to absorb curara, and another chloral. In a short time all three frogs are in a state of relaxation and inert. It becomes a question whether the muscular relaxation common to the three frogs can be taken as a basis on which to define the physiological action of each of the substances employed. To the question whether it can be said that the physiological action of curara, chloral, and strychnine consists in the abolition of voluntary motion, M. Vulpian replies in the negative, and these examples serve to show that another path must be fol-

lowed to arrive at the knowledge of the physiological action of either of the three agents used. The animal under whose skin curara was injected had complete paralysis of the voluntary and reflex movements. This condition was the effect produced by the poison; but it does not indicate the physiological mechanism of the action of curara. In what, then, does this action consist? The complete paralysis of the curarised frog may depend on an abolition of the will; but there would then be persistence of the reflex movements. The first hypothesis, therefore, is not admissible. The paralytic condition might also depend on the abolition of the functions of the medulla spinalis or the motor nerves, or result from a muscular paralysis. It is, therefore, requisite to find out which of these three cases is the true one; and when this is determined, the true physiological action of curara will be discovered. Curara, then, leaves the muscular contractility intact; for, if the muscles of the curarised frog be excited, they will be seen to contract powerfully; it does not touch the medulla, nor act on the motor nerves. It has the property of preventing the motor nerves from transmitting motor excitations to the muscles; at first, the cerebral and medullary excitations; then soon even the experimental excitations directly influencing these nerves. The effect of strychnine on the frog was to produce tetanic convulsions; caused, according to M. Vulpian, by the action of the strychnine on the grey matter of the medulla spinalis, of which it heightens the reflex properties. Proceeding to the chloralised frog, M. Vulpian investigates the cause of the torpor—the species of paralysis resulting from chloralisation. He arrives at the conclusion that chloral acts in the opposite manner to strychnine, and that it produces muscular relaxation by temporarily destroying the properties of the grey medullary matter. It is evident, then, that the physiological action of curara, strychnine, and chloral does not consist in the abolition of movement, since each of these three agents possesses a special action. The first acts on the periphery of the nervous system; the second on the grey axis of the medulla so as to excite its properties; the third acts on the same part of the medulla, but, on the contrary, weakens and even paralyses its properties. M. Vulpian then cites carbonic oxide as another example. This toxic gas, when breathed by an animal, kills it by asphyxia; and M. Claude Bernard has made clear its physiological action, by demonstrating that this gas unites itself with the hæmoglobine of the red corpuscles of the blood, and renders them absolutely unfit to absorb the oxygen in the lungs. The physiological action of a toxic substance then may be defined as the mechanism by which the effects induced by this substance are produced; these effects may be paralysis, anaesthesia, convulsions, dyspnoea, asphyxia, stoppage of the heart's action, vomitings, diarrhoea, etc. In these cases, while excepting poisoning by carbonic oxide gas, the action of the toxic substance consists in a disturbance certainly due to a histo-chemical modification of certain anatomical elements, but without any lesions recognisable by our present means of investigation. This is not so in other cases. The toxic agent leaves perfectly visible traces. It produces a lesion, and the knowledge of this lesion affords up to a certain point the key to the phenomena observed during life. It is the production of this lesion which, in a great degree at least, constitutes the mechanism of the action of poison. Take,

for instance, a man poisoned by phosphorus. He grows gradually weaker in the midst of greater or less suffering; shows various symptoms—progressive torpidity, sometimes sickness and diarrhoea, fever, icterus, etc.; and he dies at the end of a few days. Such are the symptoms of poisoning by phosphorus. The mechanism which produces these effects is indicated to us by pathological anatomy, which shows us that phosphorus induces serious lesions, steatosis of the liver, with a certain amount of interstitial hepatitis, analogous changes in the kidneys, steatosis of the muscles of animal life and of the heart, fatty alterations of the glandular epithelia of the stomach and intestines; changes in the blood, small vessels, etc.

It must not, however, be imagined for an instant that the physiological action of every toxic or medicinal substance is known. Some of the most important of these, of which the therapeutic effects are perhaps the most remarkable observed in medical practice, act by a mechanism of which the secret is absolutely unknown. Amongst these are mercury and iodide of potassium, powerful against syphilis and scrofula; such is arsenic, efficacious in cases of chronic dermatoses; and in inveterate marsh-poisoning quinine, that truly heroic remedy in intermittent fever. The knowledge of the physiological properties of toxic or medicinal substances is of great importance in medicine.

(To be concluded.)

CRICHTON BROWNE ON PICROTOXINE AND THE ANTAGONISM BETWEEN PICROTOXINE AND CHLORAL-HYDRATE.

In his experiments (*British Medical Journal*, March 27, April 3, 10, 17, and 24) Dr. Browne has demonstrated two very important matters. The first is that we have in common use amongst brewers' drugs a very powerful poison: the second is a marked instance of antagonism. He commenced first by giving a certain dose of picrotoxine to various animals, and noting the result. The effect of this poison is to produce a series of convulsions, partially epileptic and partially tetanic in character. The first indication of the action of this poison upon rabbits is a paroxysmal twitching of the ears; then follow shakings of the head and clonic spasms of the eyelids and eyebrows. After an interval the ears again commence to twitch, and then the head is drawn backwards; the spasm extends down the dorsal muscles until the rabbit sits up on its hind paws, like a squirrel when eating; all the muscles, however, are subject to clonic spasm. Ultimately the animal falls over backwards, and is convulsed. There are nystagmus, and a very decided grinding of the teeth, with a free flow of saliva and the utterance of low cries. In cases where the animal died, death is preceded by a curious movement—from lying on its side the animal suddenly rises, makes a brief scamper, and then falls finally. In cases of recovery the convulsive explosions give way to irregular, clonic spasmodic movements, with a stumbling gait, which wears off gradually.

In reviewing these experiments, writes Dr. Browne, the first reflection that occurs is that picrotoxine is an energetic poison, and that the symptoms which it produces, in one stage at least, in many respects resemble those of epilepsy. There

are sudden and paroxysmal discharges of nerve-centres in which movements are co-ordinated. The spasms first involve one group of muscles, and then involve nearly all the muscles of the body. There are changes induced in the pulse and respiration similar to those produced by epilepsy, with biting of the tongue and foaming at the mouth. After the spasms are over there is a certain amount of paralysis and loss of muscular power analogous to epileptic hemiplegia. Picrotoxine, too, leaves *post mortem* appearances, which recall those produced by epilepsy. In other respects—in the continuous, remittent discharges, in the drawing back of the head and arching of the body—the effects produced are essentially tetanic in character. In its action, picrotoxine pursues a distinct course. Its first effects are upon a region in the lower part of the frontal lobes of the cerebrum, close to the main trunk of the middle cerebral artery, and from thence the discharge extends forwards, upwards, and backwards over the hemispheres—reading the action by the light of Ferrier's researches. The violent discharges caused by picrotoxine also have another and longitudinal mode of propagation. They explode the centres which lie below them, even if these were themselves unsusceptible to the poison, though the probability is that they also are affected, but more tardily than the cerebrum. At any rate the corpora quadrigemina, cerebellum, pons Varolii, and the medulla are speedily drawn into the vortex of morbid perturbation. The occurrence of opisthotonus probably marks the time when the corpora quadrigemina begin to participate in the *émeute*. When nystagmus commences, the cerebellum is implicated; and when a sudden exacerbation in the convulsive movements takes place it may be inferred that the pons and medulla are also engaged in the terrific discharges which ensue.

Having ascertained the action of picrotoxine and learned pretty accurately the minimum fatal dose, Dr. Browne proceeded to ascertain the dose of hydrate of chloral requisite to counteract the action of the poison. For a rabbit of three pounds, the fatal dose is one-twentieth of a grain given hypodermically. Ten grains of chloral-hydrate counteract this effectually; and the antagonism which exists betwixt these two agents is one of the most pronounced upon record. When the minimum fatal dose of picrotoxine is administered, and with it ten or twelve grains of hydrate of chloral, the rabbit, instead of dying in about an hour and a half after violent convulsions, perfectly recovers after a more or less disturbed sleep of two or three hours' duration; the same rabbit is killed a week afterwards by the same dose, one-twentieth of a grain, given alone. While lying wrapt in chloral sleep, slight twitchings of the fore paws indicate that the picrotoxine is at work but is under the supremacy of the chloral; if, however, the animal be wakened out of the chloral sleep, a regular typical fit is the result. Ere the fit is repeated, sleep comes on again and arrests the explosion. In order to still further determine the antagonism, the minimum fatal dose of chloral-hydrate in the rabbit was found. It is twelve grains to each pound of body weight. For a three pound rabbit, this gave thirty-six grains as the fatal dose. One twentieth of a grain of picrotoxine secured recovery; but if the dose exceeded the minimum by four grains, the effect of the picrotoxine was insufficient to arrest a fatal issue. Some experiments were then made with cats, but chloral-hydrate was much

less powerfully antagonistic to picrotoxine and strychnine in them than in rabbits.

From the amount of picrotoxine used by brewers, in the form of *cocculus Indicus*, Dr. Browne thinks it possible that much of the epilepsy with which this country is afflicted finds its origin in drinking beer so adulterated. In Scotland, where the popular drink is whisky, there is much less epilepsy in asylums.

Dr. Browne concludes his important communication as follows. The following general conclusions seem to be fairly established by the investigations which have been described in the foregoing paper.

1. Chloral-hydrate is physiologically antagonistic to picrotoxine in rabbits and guinea-pigs, and will, when administered in a suitable and proportionate dose, save life after a fatal dose of picrotoxine.

2. The antagonism of chloral-hydrate to picrotoxine in rabbits and guinea-pigs may be exerted so as to save life, even when it is not administered until fifteen or twenty minutes after the fatal dose of picrotoxine.

3. The antagonism of chloral-hydrate to picrotoxine is subject to two limitations: *a.* That the dose of picrotoxine may be so large as to kill before the chloral-hydrate has time to operate; *b.* That the dose of picrotoxine may be so large that nothing short of a poisonous dose of chloral-hydrate would avail to counteract it.

4. Picrotoxine is, to a very limited extent, antagonistic to chloral-hydrate in rabbits and guinea-pigs, by mitigating the hypnotic effects of the latter upon the brain and higher nervous centres, which it stimulates to activity.

5. The minimum fatal dose of chloral-hydrate in the rabbit is twelve grains to each pound of body weight.

6. Practically, no antagonism exists between picrotoxine and chloral-hydrate in the cat, nor between strychnia and chloral-hydrate.

7. Picrotoxine and chloral-hydrate, when administered simultaneously to the cat, cause death by stopping the action of the heart, and not by any destructive or exhausting action upon the supreme nervous centres.

8. Chloral-hydrate causes in the cat excitement and restlessness, with motor defects prior to the state of sopor, and its effects upon that animal are protracted to an extraordinary extent.

9. The energy of the action of chloral-hydrate, as measured by its minimum fatal dose, is in proportion to the development of the cerebral hemispheres.

J. MILNER FOTHERGILL, M.D.

ANATOMY AND PHYSIOLOGY.

SCHÄFER ON THE STRUCTURE OF PACINIAN CORPUSCLES.—Schäfer (*Quarterly Journal of Microscopical Science*, April 7, 1875) has studied the Pacinian corpuscles in the mesentery of the cat. He describes the central fibre, the core, and the capsular envelope.

The central fibre he finds, as other observers have done, to resemble in most respects the axis-cylinder of a nerve, but to be sometimes accompanied for a short distance within the core by the medullary sheath. No indication of any membranous structure corresponding to the primitive sheath (Schwann's sheath) of the nerves could be found immediately

investing the central fibre. The core is not, as commonly described, alike throughout, but an outer nucleated part may in most corpuscles be distinguished from the central, almost homogeneous, non-nucleated substance, which appears, when carefully examined, indistinctly striated, and, in a transverse section, irregularly concentric. With regard to the capsular envelope, composed, as is well known, of concentric layers, Schäfer confirms in the main the observations of Key and Retzius, according to whom the supposed simple 'capsules' each consist of two layers of flattened cells, placed as it were back to back, the intercapsular spaces being filled not merely with an albuminous fluid, but to a greater or less extent pervaded by fibres both white and elastic. What have been hitherto called the capsules of the Pacinian corpuscles are not isolable without rupture of these fibres, and it is better to speak of the coat or tunic as the structural unit, meaning by this the space traversed by fibres, and the two layers of flat cells bounding it. These tunics or layers are easily separated in Pacinian corpuscles treated with chloride of gold, which coagulates the albuminous fluid, so that separation then takes place more readily between the two layers of cells of which each so-called capsule is composed, that is to say, between the tunics.

The continuity of the structures composing the entering nerve, and those of the corpuscle may be thus stated. The entering nerve and its sheath are composed of (1) the axis-cylinder; (2) the medullary sheath; (3) a delicate layer of protoplasm, with oval nuclei embedded in it; (4) the sheath of Schwann; (5) the numerous laminae composing the neurilemma. Of these, the axis-cylinder (1) becomes the central fibre of the corpuscle; the medullary sheath (2) commonly, but not always, terminates as soon as the nerve enters the core (certainly not expanding to form the core as has been sometimes supposed). To take next the sheath of Schwann (4) this, when the nerve reaches the core, expands and passes to the outer part of the core. The main part, therefore, of the latter structure is continuous with the protoplasmic layer (3) which lies inside the sheath. The extreme outermost portion of the core is formed by a layer of connective tissue lying just inside the neurilemma. Finally, the coats of the Pacinian corpuscle agree and are continuous with the layers of the neurilemma (5), the latter consisting also of an outer and an inner bounding layer of flattened cells enclosing a space, which, however, in the case of the neurilemma contains little or no fluid. The capsular envelope contains also more layers than the neurilemma, the more internal being, as Schäfer thinks, those that are superadded.

KIDD AND BRANDT ON SPONTANEOUS MOVEMENT OF NUCLEOLI.—Kidd (*Quart. Journ. Micr. Science*, April, 1875, vol. xv. n.s. pp. 133) noticed that the nucleoli of certain epithelial cells from the frog's mouth presented a crenated appearance, which, on closer observation, turned out to be due to spontaneous amoeboid movements of the nucleolus. Processes were observed given off from the nucleolus, sometimes furnished with a knob at the end, and sometimes branched. Occasionally they returned into the body of the nucleolus while others were formed. The cells in which this took place were large, pale and non-ciliated, not lymphoid but looking like young epithelial cells. They were examined in aqueous humour on the hot stage.

Brandt (abstract in same journal, p. 182) had

previously observed ameboid movements leading to both change of form and locomotion in the nucleolus (germinal spot) of the ovum from the ovary of *Blatta orientalis*. The movements were slow but stimulated by heat.

Similar observations have been made by Balbiani, L. V. St. George, and others.

MEDICINE.

FERRARI-BRAVO AND VALTOSTA ON A CASE OF PARACENTESIS OF THE PLEURA, ABDOMEN, AND PERICARDIUM.—This case is related in the *Giornale Veneto di Scienze Mediche* for March, 1875. On August 5, 1874, a man named Natale Ruffio, aged thirty-five, a weaver, was admitted into the civil hospital at Treviso. He was of middle height and slender make, with defective nutrition, wasted muscles, and a yellow-brown skin. Four months previously, after very fatiguing labour, he had been attacked with continued fever, accompanied with cough and copious expectoration, dyspnoea, swelling of the lower limbs, and extreme weakness. On examination there was found to be dulness over the whole left half of the chest, and the lower part of the right half. The breath-sound was bronchial and harsh on the left side, and exaggerated on the right. In the abdomen the spleen and liver, especially the former, were enlarged. The spleen reached the middle line, and extended a finger-breadth below the umbilicus. He had long resided in a damp dwelling, badly ventilated, and altogether unhealthy, and the symptoms and physical signs pointed to the existence of malarial cachexia. Restorative treatment was ordered, with digitalis, to strengthen the force of the circulation. Up to August 13 the state of the breathing did not cause much anxiety; but on the subsequent days he had urgent dyspnoea, amounting at last to orthopnoea; there was very extensive dulness on percussion, the vesicular murmur was lessened, and the beat of the heart was scarcely perceptible. No relief being obtained by stimulants and restoratives, the left side of the chest was tapped, and about two litres of fluid escaped. The patient felt relief for three days, but then again became worse, and the secretion of urine was suspended. The puncture was therefore repeated, and gave exit to a litre and a half of serum; this was followed by relief which lasted about a month, during which time the patient became able to leave his bed, complained of little except a cough at night, and gained about three and a half pounds in weight. The spleen, however, remained enlarged; his breathing was not completely free, and his speech was always somewhat interrupted. Quinine and iron were given daily for about two months. The quantity of urine varied much, but there was never complete suppression. After this, iodide of potassium was given for a time, but was not well borne.

At the end of September, signs of abdominal effusion began to appear, being attended with scantiness of urine. His condition was again improved under the use of moderate doses of iodide of potassium, given for about a fortnight; but during the early part of November (perhaps in consequence of changes in the weather) severe respiratory symptoms set in, and were kept up by the pleural and pericardial effusion, and still more aggravated by the ascites. Drastics were given with the effect of producing copious alvine evacuations and reducing the effusion; so that, on November 14, the breathing was found to be more free in the right lung and in the posterior part of the left; but there was a harsh sound in the former, and the area of cardiac dulness was still enlarged. The patient himself said that he breathed more freely, and that he perceived a diminution of his abdomen.

About the middle of December, the breathing again became difficult, the urine was scanty, and ascites had increased; paracentesis abdominis was, therefore, performed on December 17, and between fifty and sixty ounces of a citrine yellow fluid were removed. The operation was at first followed by relief; but three days later the urine began to be scanty, and neither tonics nor digitalis improved the patient's condition. Painting with tincture of iodine was employed, but no good followed. Fever set in, at first erratic, but afterwards constant. The signs of effusion in the three cavities increased, and the general symptoms became much aggravated. Quinine and alcohol were given with only temporary relief. On December 30, paracentesis pericardii was performed by Dr. Valtosta. A fold of skin having been raised over the fifth intercostal space, an incision a little more than an inch long was made parallel to the ribs, in the centre of the space, commencing about two-fifths of an inch to the left of the sternum. The layers of muscle were then carefully divided, and an elastic dilatation was felt, which resisted a little under pressure, while the impulse of the apex of the heart could be indistinctly perceived. A puncture having been made in this, the point of a small trocar was introduced, and about ten ounces of fluid were removed, with immediate relief. On examination after the operation, the upward limit of dulness was found to be lower. The heart-beat could be felt, and the sounds heard, much more distinctly than before. The patient changed his position more easily; he was able to lie nearly horizontally; his pulse became full and strong; he slept well in the night and for several hours the next day. After four days, however, signs of effusion in the pleura again appeared; and on January 4, more than eight ounces of fluid of the same character as before were removed by paracentesis. On the 9th, the urine became scanty; the temperature, after some oscillations, rose to 104°; and he had painful cedema and redness of the left buttock, hip, and leg, on which he had lain for some time. No relief was afforded by local remedies or quinine; his cough became very troublesome; the dyspnoea increased; and, after lying for twelve hours in a state of coma, he died on January 14.

At the necropsy, the body was found to be extremely emaciated, but not in a state of marasmus. On removing the cartilage of the fourth and fifth ribs on the left side, a very little purulent exudation was found between the layers of the pleura. The anterior surface of the pericardium was distended, had a yellowish colour, and presented a small

point of the size of a pin's head, which, on the introduction of a probe, gave exit to serum. About two litres of serous exudation were found in the pleural cavities, mostly in the left. The left lung was strongly compressed towards the base of the thorax, and was scarcely one-third of its normal size. The right lung was more expanded, and contained tubercles in various stages in the upper and middle lobes; there were no caverns. The pericardium extended from about 1.2 inches on the right margin of the sternum to about 2.75 inches on the left. On section, it was found to be four times as thick as natural; and about a litre and a half of citrine yellow fluid escaped. The heart was somewhat enlarged, and was covered with white glistening adherent fibrinous deposits. There was concentric hypertrophy of the left ventricle; the valves on both sides were healthy. There was a little serous fluid in the abdomen; the liver was enlarged, congested, and indurated; the spleen was remarkably enlarged, congested, and diffuent; the kidneys, especially the right, were rather hyperæmic.

A. HENRY, M.D.

GOURLEY ON A CASE OF PERITYPHLITIC ABSCESS DUE TO PERFORATION OF THE APPENDIX VERMIFORMIS.—In the *Virginia Medical Monthly* for March, 1875, is a paper on the above subject which was read before the Medical Society of New York by Dr. J. W. S. Gourley. The patient was a gentleman, thirty-seven years of age, who had suffered from right oblique inguinal hernia for two years, and had worn a truss, but at times with considerable inconvenience. On two occasions the hernia had become irreducible, but yielded to rest in the horizontal position, fomentations, etc. There was a history of his having swallowed a tooth two years before the attack of typhlitis. In June, 1873, he had unusual and severe pain in the right iliac region and fossa; he was constipated, and there was constitutional disturbance; a swelling followed in which no fluctuation could be detected, but it ended in an abscess, which in August opened spontaneously; after this, the patient rapidly got better, and remained so until February of 1874, when he had another attack of pain and great swelling in the right iliac region, and deep-seated fluctuation was made out. Dr. Gourley then advised 'incision, as for ligation of the iliac artery,' and after a few days waiting this was done. He thus describes the operation. 'An incision six inches in length was made parallel to and one and a half inches above Poupart's ligament, cutting down layer by layer to the fascia transversalis; the abscess was freely laid open, from which about a pint and a half of fetid, flaky pus escaped.' No foreign body was discovered; but at the bottom of the wound a faecal concretion about the size of a horse-bean was found. This was at first supposed to contain some foreign body, but it did not; the cavity was filled with lint, and it gradually and completely closed by the middle of May. The patient has continued well.

In his remarks on the case, Dr. Gourley puts the question—Did the typhlitis result from the hernia? and answers this in the negative, for the reason that the abscess did not point in the inguinal canal; nor does he think that undue pressure of the truss caused it. On the whole, he is strongly of opinion, although the swallowed tooth was not found, that some foreign substance was the occasion of the abscess; and the faecal concretion found in the cavity of the abscess

must have escaped from the vermiform appendix. On the point of treatment, the author insists on the advantages of making an early and very free opening into the abscess, and filling the cavity with lint, so that slow granulation from the bottom should take place. He quotes the opinion of Dr. Willard Parker, that, if the patient live over five days, it may be inferred that sufficient adhesions have formed to circumscribe the pus until it accumulates in large enough quantity to break through them. Dr. Gourley says that, when an obstinate faecal fistula remains, it may be assumed that perforation of the cæcum, and not of the appendix, has taken place.

The prognosis in this affection is bad, especially when the foreign body drops into the peritoneal cavity; in these cases also, the author thinks the best chance is afforded to the patient by timely interference, as recommended by Dr. Lewis in a paper in the *New York Medical Journal* for November, 1856. Dr. Gourley enters somewhat fully into the literature of the subject, and instances cases of Dr. Willard Parker, Mr. Hancock of London, and many others. WM. ALLINGHAM.

PREVOST AND DAVID ON A CASE OF ATROPHY OF THE RIGHT THENAR EMINENCE WITH LESION OF THE SPINAL CORD.—The following case is reported by J. L. Prevost and C. David, of the cantonal hospital at Geneva (*Archives de Physiologie*, September, 1874). M. Prevost observes that it constitutes a fresh example of the muscular atrophy limited to one group of muscles, and having a corresponding limited lesion of the spinal cord. In 1865, the author presented an example of atrophy of the muscles of the leg, with lesion of the grey matter of the anterior horn of the same side. Until then, he adds, no observer had pointed out, as traced by himself and M. Vulpian, the disappearance of nerve-cells from the external group in the anterior horn, in muscular atrophy. Subsequently this connection has repeatedly been noticed, both pathologically and experimentally produced. Dr. Prevost sums up the lesions as consisting of, 1. Distinct atrophy of the right anterior root of the eighth pair of cervical nerves; 2. Slightly marked atrophy of the right anterior root of the seventh cervical nerves; 3. Atrophy of the grey matter of the anterior horn at this level, extending two or three centimètres in length (about one inch).

Louis F., sixty years of age, pianoforte-maker, was admitted March 26, 1874, with a wound of the scalp, and died from putrid fever on April 7. He asserted that the atrophy of his thumb had existed from infancy, that he had not suffered any pain from it, but had not been able to execute the movements of opposition. On *post mortem* examination, the thenar muscles were found to have been transformed into thin masses of white fatty substance. Some few muscular fibres could be isolated. In these the striæ still existed; in other parts there remained only large fat-cells, limited by connective tissue. On the palmar face of the eminence a thin layer of muscular structure was found, probably the remains of the adductor pollicis. The first dorsal interosseous muscle, along the border of the index metacarpal bone, was completely atrophied and transformed into fat. All other muscles of the hand and forearm were perfectly healthy. The hypothenar eminence in particular was observed to be intact.

The only abnormal appearance in the nerves of the affected limb was an excess of connective tissue in those supplying the thenar eminence. The roots of

the eighth cervical nerves at their exit from the spine on the right were much more slender and contained fewer fibres than on the left side. Corresponding with this diminution of the nerve-roots were certain changes in the grey matter of the spinal cord. These changes were evident to the naked eye, consisting in a manifest diminution of the size of the anterior horn on the right side, the difference becoming less above and below, until it merged into the normal structure. [These graduations are graphically represented in the plate which accompanies the paper.—*Rep.*] At the level of the eighth nerve there were but a scattered few of the cells of the external group, in the anterior horn. Departing from this point, upwards and downwards, the nerve-cells were observed to be reduced, in some parts, to a mere trace of their structure. At the seat of this lesion of the cells the substance of the cord was altered, presenting a granular fibrillated character, remarkably fragile, and taking the carmine tint deeply. So brittle was the cord at this point, that it was almost impossible to obtain perfect sections. This brittleness occasioned tearing and fissures recalling to the mind of the authors the appearances described by Dr. Lockhart Clarke as 'granular disintegration.' The white substance of the cord on the right side appeared to have undergone a slight or incipient degree of sclerosis. Amyloid bodies were in great numbers in the seat of this change. The posterior right horn was not affected beyond presenting a great number of amyloid bodies in the tracts of vessels. The central canal was filled with nuclei and corpora amylacea.

The preceding case, with its pathological history, is placed by the authors in the same category with others recorded by Cornil, Vulpian, Damaschino, Roger, Charcot, Joffroy, Pierret, Müller, Lockhart Clarke, Duchenne, Petit and Roth. It proves, they hold, that lesions of the nerve-centres give rise to muscular atrophy, as confirmed by experiments in which the sequence occurred, and in the face of which, they hold, it is difficult to assign a secondary character to the medullary lesion. They admit that the original nature of the lesion cannot in the present instance be determined. It is probable that the subject of these observations was addicted to drink, a condition favouring the premature degeneration of tissues. A physiological interest further attaches to the present case inasmuch as it serves to demonstrate the nervous supply to the thenar muscles to be from the eighth cervical nerve.

[A full and instructive narrative of a case of like nature to the preceding, was communicated by Drs. Adamson and Oswald Bell to Beale's *Archives of Medicine*, vol. iii., accompanied by an elaborate exposition, from the pen of Dr. Lockhart Clarke, of the pathological changes found in the spinal cord. This history, thus published in 1861, was the first recorded account of the lesions of the nervous centres connected with muscular atrophy.—*Rep.*]

W. B. KESTEVEN, M.D.

NORRIS ON OPTIC NEURITIS.—Dr. W. Norris, of Philadelphia, has published two cases of optic neuritis occurring with intracranial disease, in both of which the discs were examined microscopically after death. The report is accompanied by large coloured lithographs of the morbid appearances. The first patient, a clerk aged twenty-eight, came under care in November, 1873. He gave a history of attacks of severe occipital pain, nausea, frequent vomiting,

and gradual enfeeblement for two years. Latterly his sight had become dim. When first seen he was pallid and obese, his intellection was 'slow but unimpaired.' His hands were feeble and tremulous, his gait very tottering. Both pupils were partly dilated, both external recti partly paralysed, the right more. In walking towards an object he turned considerably to the left. With the right eye he could count fingers at a few feet. Vision in left eye was $\frac{10}{6}$. The discs were very prominent and their normal boundaries obscured. In both there was a large development of capillary vessels; the right was beginning to atrophy, having already acquired a bluish white tint. The summit of the right disc was visible with $+\frac{1}{8}$, that of the left with $+\frac{1}{12}$, and the fundus near the equator of each eye with $+\frac{1}{4}$. He had paroxysms of intense headache in which his pulse would vary from 90 to 116, and his temperature from 98° to 100.5°. He had morning vomiting. Then occurred a transient attack of universal powerlessness, partial loss of motion and sensation on the right side of the face and gradually increasing loss of vision. The paroxysms of headache were always attended with marked deterioration of sight. He gradually became weaker and weaker, and died six months after he came under care. On necropsy, a tumour was found extending transversely through the cerebellum. Judging from the lithograph, its total bulk must have been about that of a hen's egg. Microscopic examination showed that the disc (which side is not specified) measured $\frac{1}{20}$ th from the level of the choroid to the summit of the papilla. The lamina cribrosa was also swollen, bulging forward, and the whole tissue stained far more intensely with carmine than a healthy adult nerve; closely resembling, indeed, the optic nerve of the foetus. The nerve-fibres showed numerous spindle-shaped swellings which stained deeply with carmine, and in the interstitial connective tissue were very numerous nuclei with newly formed blood-vessels.

The second patient was a young woman, aged twenty-three, who had symptoms of lead-poisoning from using white lead as a cosmetic. For two months only before she came under care she had suffered from headache, loss of appetite, violent gastric pain, nausea and vomiting. On admission there was a marked blue line on the gums. Soon after she was seized with epileptiform convulsions, and in the third she died. Ophthalmoscopic examination between paroxysms showed that the disc was prominent, its outline hazy, its colour an opaque bluish-white, the sclerotic ring not visible, and the vessels diminished in calibre. Beyond anæmia of the brain-substance and a marked increase of cerebro-spinal fluid there were no naked eye changes found in the brain. The sheaths of the optic nerves were distended. Microscopic examination showed numerous capillary vessels throughout the swollen disc, and a moderate development of the nuclei of the connective tissue. There were none of the spindle-shaped swellings of the nerve-fibres found in the former case.

In both of the cases, sections of the posterior parts of the optic nerves were compared with those of the optic entrance, and in both the increase of interstitial connective tissue and deep staining of its nuclei, though most marked in the latter position, extended throughout the length of the nerve.

[This paper is a valuable contribution both to clinical medicine and to ophthalmology. The author thinks that tumours of the cerebellum and

of the posterior parts of the hemisphere are more apt to produce 'choked disc' than those of the anterior lobes. Tumours of the posterior lobes are, in the reporter's experience, rare; he thinks that tumours, whether in the anterior lobe or in the cerebellum, almost always produce changes in the optic nerves. These changes the reporter calls optic neuritis; contrary to most, if not all, other writers on the subject, he believes that there is but one kind of acute change from tumour in any part of the encephalon. He does not think that swelling of the optic nerves is produced by raised intracranial pressure. There are, he thinks, but two kinds of ophthalmoscopic changes seen from intracranial disease, optic neuritis from tumour, and swelling of the discs (from, as he believes, thrombosis of the veins) in some cases of meningitis. In a few cases of neuritis, with great swelling, there is no discoverable intracranial disease. We repeat that the author's paper is a contribution of great practical value. The careful estimation of degrees of swelling of the discs is worthy of imitation.—*Rep.*]

J. HUGHLINGS JACKSON, M.D.

WELCH ON THE NATURE, VARIETIES, AND ETIOLOGY OF PULMONARY CONSUMPTION IN THE ARMY.—The following are some of the main conclusions arrived at by Mr. Welch, Assistant Professor of Pathology at Netley, in his thesis on the 'Nature and Varieties of Destructive Lung-Disease included under the term Pulmonary Consumption, as seen among Soldiers, and the Hygienic Conditions under which they occur' (*Alexander Prize Essay*, 1872). All the varieties of military phthisis are divisible into three groups, viz: 1. Inflammatory and idiopathic, with a sub-group of inflammatory specific; 2. Specific, textural; and 3. Alien, consequential, or ingrafted. By far the larger number of cases, viz., 73·81 per cent. (out of a total of 230 cases) fall under the first head, which includes pneumonic (lobar, lobular, and hæmorrhagic) and bronchitic (acute and chronic catarrhal) phthisis. The sub-group of specific inflammatory lesions yields 9·53 per cent., and is confined to pneumonic and bronchitic phthisis of syphilitic origin. The second group, comprising syphilitic gummatous phthisis and tubercular phthisis, was met with in 11·28 per cent., the numbers being equally divided between the two specific textural lesions indicated. The last group—made up of dysenteric, pyæmic, embolic, and diabetic phthisis, with phthisis from local irritation (*e.g.*, grinder's phthisis) gives 5·14 per cent. An exhaustive analysis of each form of phthisis follows, many illustrative cases being given with full detail. The lobar pneumonic form occurred in six per cent. of the cases, the subjects attached being of all ages and of previous good health. The limitation of the disease to one lung, generally involving the base, and its frequent association with hæmoptysis, which often proved fatal, are considered to be the distinctive characters of this form. Phthisis originating in lobular pneumonia occurred in 26 per cent., and was marked by an insidious origin, the apex being primarily attacked and both lungs usually involved, the disease mostly taking a chronic course. Under 'hæmorrhagic phthisis' are included 17·28 per cent. of the cases, occurring in subjects free from tubercular or strumous diathesis, and leading directly to pneumonic changes, without the development of miliary tubercle. The hæmorrhage is attributed to delicacy in the pulmonary capillaries, chiefly induced by constric-

tion of the chest. The catarrhal or bronchitic variety, characterised by an antecedent bronchitis, was met with in an acute form in 15 per cent., and in a chronic form in 8 per cent. It is stated that in all the cases included within this first group there was no question of tubercular or other diathesis, and almost entire freedom from any predisposing cause, so that they could mostly be held to depend upon the hygienic conditions peculiar to military life. In many of the cases tubercular changes occurred secondarily. The pathology of these cases is fully described, together with an analysis of the associated lesions met with in 'inflammatory' phthisis. Intestinal lesions are ascribed to catarrh, although a secondary tubercular change is admitted. Syphilis as a cause of inflammatory phthisis, arising either in pneumonia or in bronchitis, is held to be proved in many cases; and the extreme frequency with which evidences of phthisis are met with in the subjects of syphilis dying from other causes is insisted on in support of this, together with the fact that in most cases the symptoms of the lung-disease followed exposure to syphilitic infection. The truly specific lesion of visceral syphilis, viz., the gumma, was met with in 5·6 per cent. of the cases; the characters of this 'gummatous phthisis' being previous inoculation with the syphilitic virus, followed at a late period by pulmonary symptoms, the extreme variability in site of the destructive lesion, with the existence of gummata and chronic inflammatory changes. The histological distinctions between the syphilitic and tubercular nodule are based chiefly upon the presence of well-defined spindle-cell forms merging into fibrous tissue in the former, contrasted with the small round-cell elements imbedded in fibrous matrix in the latter. Purely tubercular phthisis was of rare occurrence, and was always preceded by a term of ill-health. A few pages are devoted to the forms of phthisis included under the third group. The exigencies of military service as a factor in the production of these different forms of phthisis are then fully described; the vitiated atmosphere of barracks being held to be accountable for nearly one half of the whole number of cases, combined with exposure to climatic variations, and constriction of the chest from accoutrements, etc.; and the essay concludes with an urgent appeal for reform in these directions, much of the pulmonary disease met with in the army being clearly traceable to preventable causes.

SIDNEY COUPLAND, M.D.

KRAMER ON TWO INTERESTING CASES OF VARIOLA.—The first of these cases, which are reported by Emmanuel Kramer in the *Vierteljahrsschrift für Dermatologie und Syphilis* (1874), was that of a young man, aged seventeen, admitted to the small-pox hospital at Vienna on June 13, 1874, on the fourth day of his attack. Vesicles were disseminated all over the body, and were beginning to change into pustules here and there. There was diffused erythema all over the body, most intense at the level of the right femoral triangle; it disappeared on the 15th. On the 17th, the eighth day of the illness, there was a scarlatinous redness of the whole body, deepest on the pelvis, arms and thighs. Redness, with punctured ecchymoses on the velum palati and adenitis of the cervical glands, especially on the left side, were also present. Some of the variolous pustules were in a state of suppuration, whilst others were already dried up. The urine contained albumen. Temperature 103·6°

Fahr. On the 18th the variolous eruption was dried up; there was double submaxillary adenitis, with a little albumen in the urine. Temperature $104^{\circ}72^{\circ}$ Fahr. On the 20th there was a miliary eruption at the bend of the elbow; on the 23rd the scarlatinous eruption began to desquamate; on the 27th erysipelas of the face made its appearance, but disappeared very rapidly. Convalescence set in at the beginning of July, but the patient had two attacks of erysipelas in the face, one on July 20, the other on the 29th; both, however, were extremely mild and almost apyretic.

The second case was one of variola immediately consecutive on a previous attack. The patient was a young man, aged eighteen, who came into the small-pox hospital on the fifth day of an attack of variola discreta. The pustules began to dry up at the end of a week. On the sixteenth day after the appearance of the disease the patient had violent shivering, a temperature of $103^{\circ}8^{\circ}$ Fahr. and lumbar rachialgia. On the twenty-ninth day there was diffused generalised erythema, and at night the fever rose to forty degrees. On the thirty-first day variolous efflorescences made their appearance on the face, hands, and feet. The first signs of the drying up of the fresh eruption appeared on the face on the thirty-fourth day, and recovery ensued without any accident.

OPHTHALMOLOGY AND OTOLOGY.

NIEDEN ON NYSTAGMUS AS THE RESULT OF HEMERALOPIA.—The *Berliner Klinische Wochenschrift* of November 23, 1874, contains an account of some very remarkable cases of this kind which had occurred in the practice of Dr. Nieden of Bochum. This distressing affection of the muscles is unfortunately very commonly met with in the eyes of children, and although most writers would allow the possibility of its occurrence during adult age, yet they would attribute it to some congenital peculiarity, or to some disease contracted in very early life. In the instances here brought forward no such history was forthcoming; and at first sight Dr. Nieden was at a loss to account for the phenomena, occurring as they did under such extraordinary circumstances. The cases, six in number, are reported in great detail, and until we reach their explanation it is certainly remarkable that in no single instance was any structural alteration to be found in the eye either within or without; and the correctness of the diagnosis in each instance was verified by the cure which appropriate treatment was able to bring about.

H. B., aged thirty, a miner by occupation, applied for advice in February, 1874, and complained that for the last year he had been annoyed by a mist before his eyes, which he first noticed whenever he entered the mine and hung up his lamp at some distance from his work; for some short time he could look at the lamp without difficulty, but he

then found the light begin to dance and to flit to and fro; he then became giddy and was compelled to shut his eyes. This gave him relief, but only for a time. When this state of things had lasted for a month, he noticed that his eyes had lost their power of fixation when he looked at any distant light, on his way to his work in the dim light of early morning; any effort on his part to steady his eyes immediately brought on headache and vertigo. As time went on, he found that his vision failed him after sunset, that he could read only with difficulty, and the light of his room was altogether insufficient; and yet in broad daylight and in sunshine his sight was perfect in every way. Except that he looked anæmic, there was nothing remarkable in his appearance. His eyes appeared normal in every way when first examined by daylight; their movements were perfect and entirely under his control; their vision was $\frac{1}{12}$, and they read Snellen $1\frac{1}{2}$ at 18 inches fluently. The field of vision and perception of colours were normal. So far, it was hard to say what was the nature of the affection. In the hope that the ophthalmoscope might reveal some structural change, the room was now darkened, and at once the symptoms such as he describes made their appearance. When he looked across the room, his eyes began to oscillate with extreme rapidity from left to right, and after a few moments he was compelled to shut them. When either eye was examined singly, the result was the same. His vision by this artificial light had fallen to $\frac{1}{2}$, and he could only read Snellen VI. with difficulty. The field of vision was not diminished, but the perception of colours was less acute. The ophthalmoscope revealed absolutely nothing abnormal. The daylight was again admitted into the room, and his symptoms disappeared once more. He regained control over his eyes, and his vision again was $\frac{1}{12}$. The existence of well marked hemeralopia was thus evident; and although it could not be shown that the eyes of miners are especially liable to it, yet in the nature of this man's employment it was easy to read the explanation of its development. While at work in the mine, his eyes were accustomed only to very dim and imperfect illumination, and the sudden change to the bright light of the sky above which occurred daily was sufficient in time to exhaust the power of the retina to such an extent that it was unable to convey impressions whenever the sun went down, and when the man attempted to do anything by artificial light, or by any light less than that of broad day. To account for the nystagmus was not so easy; but from the man's own account, Dr. Nieden was inclined to believe that exposure to cold from draughts, and to foul air within the mine, had much to do with its production.

A second patient, from the very same pit, applied on the following day, with much the same complaint; the nystagmus, in his case, was around the horizontal axis of the eyeballs, whereas in the first case it had occurred mainly around the vertical axis. This man also was well in health, and his eyes presented no appearance whatever of disease, except their failing vision and their irregular movements under the circumstances above mentioned.

A third patient from another mine presented himself; in substance his condition and his symptoms were such as have been described; but in his case the condition of the mine could have had no influence, for its temperature and its ventilation were as perfect as it was possible to maintain them. A further illus-

tration how nystagmus may develop in eyes which are affected with hemeralopia, and these not the eyes of miners or quarrymen, may be seen in Case 6, which Dr. Nieden records.

A timber hewer, aged forty-seven, was for years much exposed to wind and weather during the spring and summer months; much of his work was over a saw-pit, where, for hours together as top-sawyer, he was compelled to fix his eyes steadily upon his saw. In bright sunshine, the reflection from this and from the smooth surfaces of the planks was very dazzling and fatiguing, and in the course of time he found that on a cloudy day his vision appeared much diminished, and, on looking around him, especially when evening came, all objects became unsteady, and he saw them double. During the winter time, when he was otherwise employed, these symptoms disappeared, to make themselves felt again, however, on the first spring day when he resumed his work. On examination by daylight his vision was nearly normal, with presbyopia = $\frac{1}{36}$ th, and oscillating nystagmus whenever he directed his eyes to any distant object; when the room was darkened his vision sank to $\frac{1}{6}$ th; in appearance, and in all other respects his eyes were normal.

It is characteristic of all the cases here recorded, that the irregular movements of the muscles appear to have arisen in consequence of the effort to compensate for the weakened power of the retina by increased exertions on the part of the muscles required for fixation, and also that no one pair of muscles was affected, but each and all of those supplied by the third pair of nerves, including the superior oblique. It is, therefore, impossible to classify them with those instances of hemeralopia which were described by Von Gräfe (*Archiv für Ophthalmologie*, vol. v. part 1) as being associated with insufficiency of the internal recti, inasmuch as in every one of them the failure in the muscles was displayed during distant vision, and, provided the light were good, the power of convergence and of reading was unaffected. Nor did any of the cases present those fatty growths beneath the conjunctiva similar to pinguecula, such as Bitot has described as characteristic of hemeralopia.

The treatment adopted appears to have been eminently successful; the eyes were protected by grey glasses, and strychnine was given continuously for some days by means of hypodermic injections. In one case only, in which the symptoms were of long standing, was it thought necessary to supplement this by the use of the continuous current, with the strength of six cells at first, increased subsequently to a strength of eight and of twelve cells. By these means, complete relief was in the end attained.

LANDSBERG ON DOUBLE-SIDED PARALYSIS OF THE OCULAR MUSCLES.—Dr. M. Landsberg (*Berliner Klinische Wochenschrift*, December 21, 1874), remarks that the paresis or paralysis of one or more of the muscles of the eyeball is very often a clue to the nature of intracranial disease, inasmuch as the particular muscles implicated, or the order in which several are successively implicated, and the temporary or permanent derangement of its functions are all of importance in enabling us to understand the nature of the case with which we have to deal. Von Gräfe (*Archiv für Ophthalmologie*, vol. xii.) has left upon record the details of several cases in which paralysis of one or more muscles upon each side had been noticed, and he has expressed the opinion that

the explanation of these and similar cases is to be found in the existence of periostitis at the base of the skull. On the other hand Michel (*Klinische Monatsblätter*, 1872) has described an instance of double-sided paralysis of the third pair, in connection with rheumatic fever, which, he concludes, was due to hyperæmia of the meninges and consequent effusion of serum. Landsberg is unable to endorse the opinion of Von Gräfe on this point; and in the paper before us he has published the details of several cases which he cannot include in the category as being due to periostitis.

Case 1.—Louis S., having previously enjoyed very good health, took a sudden chill after dancing, in the middle of September, 1873, and during the same night was seized with intense pain in his eyes, which rendered it impossible to move them without moving his head at the same time. The next morning he saw double, and was still in pain; but the pain left him in the course of the next few days. The double vision, however, remained, and became more and more annoying because the images appeared oblique. He presented himself to Dr. Landsberg on October 12, who found absolute immobility of both external recti muscles; the movement inwards of the eyes was limited to 1''; while the movements upwards, and upwards and outwards, and downwards, were altogether abolished. The fourth pair appeared to be involved also; but the movements of the eyelids, and the action of the pupils and the accommodation, were not affected on either side. The acuteness of vision was normal. The double images were not always noticed, in all probability because of the great distance which intervened between them. With the exception of the pain in the eyes, the patient had nothing to complain of, his general health not being impaired. The treatment consisted in the administration of tartar emetic in nauseating doses; and at the end of three days the patient could move his eyes upwards and inwards, the improvement being more marked on the left than on the right side. The same treatment being persevered with, the improvement was maintained; and by the end of October considerable power of movement outwards had returned. Owing to some degree of permanent contraction taking place in the internal recti, there was for some time a slight degree of strabismus. With the aid of the continuous galvanic current this was eventually overcome, and by the end of January the patient was in every respect well again.

Case 2.—Herr Z., aged forty, consulted Dr. Landsberg on August 21, 1873, having suddenly been seized with pain in the orbits, followed by diplopia, about eight days previously; he had up to this time enjoyed very good health, and had never suffered from rheumatism or syphilis. On examination, it was found that the external rectus of the left eye had lost its power, and later on, when the case had been under observation some days, it was evident from the nature and position of the diplopia that the corresponding muscle on the right side was also affected. The recovery of this patient, though eventually complete, was but slow, and did not appear to be materially assisted by any remedies employed.

In the former of these two cases it is difficult to suppose that the cause could be referred to any basilar periostitis such as Von Gräfe has suggested, and Dr. Landsberg inclines very strongly to the opinion that the mischief was rheumatic in its origin. But as regards this latter case, while we cannot suppose

the existence of any intracranial periostitis, there is no reason to refer it to the category of rheumatic affections. The third case is recorded as the type of a double-sided paralysis, due in all probability to the occurrence of intracranial hæmorrhage.

Case 3.—Ida B., aged fourteen, was brought to Dr. Landsberg by her mother in September, 1871, who said that a fortnight previously the child had fallen upon the back of her head; she was stunned at the time, and when at length she recovered her senses she complained of severe headache and of seeing everything double. During the last few days the diplopia had been less noticed, but the pain was persistent. On close examination it became evident that both the external recti muscles had lost their power over the eyes, and that diplopia was always present under certain conditions. In the course of time a secondary contraction of the internal recti occurred, but was in its turn overcome. No other muscle was affected, and neither the action of the pupil nor the accommodation was interfered with. In the course of a few weeks the child had completely recovered, no signs of cerebral disease or even cerebral disturbance having manifested themselves.

BOWATER J. VERNON.

PAGE ON TRANSMISSION THROUGH THREE GENERATIONS OF MICROPHthalmOS, IRIDEREMIA, AND NYSTAGMUS.—In the *Lancet* of August 8 appears a short, but very interesting account, by Mr. Page, of the transmission through three generations of microphthalmos, irideremia, and nystagmus. The literature of the subject appears to be neither very copious nor satisfactory. Boehm records, in a monograph on nystagmus, an instance in which there was a tendency to albinism and consequent nystagmus in a family, gradually increasing in intensity from a blue-eyed mother, with colourless eyebrows and eyelashes, through a daughter, to a granddaughter, 'whose hair was originally as white as well-bleached linen.' He mentions also the occurrence of nystagmus in a family of six brothers. Gadaud gives a summary of five theories as to the nature of nystagmus.

In Mr. Page's case, that of a girl, aged fifteen, there were an almost total absence of the irides, smallness of the globes and corneæ, and constant nystagmus. The movements of the eye-balls were 'in general rotatory, and only occasionally horizontal, the latter having the appearance of being caused by strong sharp tugs of the external recti muscles.' Her mother, who suffered from the same affection, had children in the following order:—1. Daughter, with defect, and mother of daughter with like defect; 2. Son, died of 'water in the head'; 3. Son; 4. Daughter; 5. Daughter; the patient in question. The hair in these members of the family is brown, but of different shades in each. None of the parents were relations.

Mr. Page does not consider the views respecting nystagmus, put forth by Boehm and Gadaud, to be satisfactory, and seems rather to incline to the conclusions of Dr. Ferrier, founded upon his now well-known experiments, made in the West Riding Asylum, that this condition is an epileptiform affection of the oculomotorial centres, located in the cerebellum, and reasonably enough remarks that 'as far as transmission goes, there seems to be no more reason against an hereditary abnormality of the cerebellum than against an hereditary abnormality of the eyes themselves.' [It may be worth while to mention, as

bearing upon what has just been recorded, that there is, or very lately was, in the garden of the Zoological Society, an albino monkey, labelled 'white variety,' belonging, if our memory serve us aright, to the genus *Macacus*, in which some slight nystagmus of the eyeballs could be observed. Mr. Boyle, in his work *Through Fanti Land to Coomassie*, states that, so far as his experience goes, all albinos in the tropics are idiotic. It would be interesting to know whether this is supported by any medical evidence.—*Rep.*]

J. C. GALTON.
